creased by adding solid food at short intervals, but there must be no overloading of the digestive organs. In the beginning a loss of three to five pounds a week may be obtained, but when the effects of this become evident, the diet should be adjusted so that but three to five pounds a month are lost. After a few months' treatment more freedom in diet may be allowed for a few months. Then the diet should again be restricted so that a gradual loss of weight results. This method should be persisted in until the weight normal for the individual is reached. The essayist finds that after a patient has undergone the course of treatment his dietetic habits have been corrected to such an extent that he is not likely to resume the habits responsible for his obesity as he so frequently does after a few weeks' treatment in a sanatorium under artificial surroundings. A number of cases are cited illustrating the course and results of this treatment.

5. **Report on the Clinical Symptomatology and Laboratory Findings in Three Cases of General Paresis under Intravenous Arsenobenzol Treatment.**—G. E. Mott and S. M. Bunker state that hitherto the diagnosis of general paresis has been made upon the appearance of such classical symptoms as the Argyll-Robertson pupil, altered knee-jerks, ataxia, loss of judgment, emotional instability, etc. Now they have come to look for the following six laboratory tests in confirmation of the diagnosis of general paresis: 1. Positive colloidal gold reaction of Lange. 2. Globulin—present and increased, Noguchi—butyric acid method. 3. Albumin —present and increased. 4. Number of lymphocytes per c.c. increased from 10 to 400. 5. Wassermann reaction of the blood serum. 6. Wassermann reaction in the spinal fluid. The recent work of Southard and other observers tends to show that the six positive laboratory findings are present months and perhaps years before the appearance of the classical clinical symptoms. In the cases reported arsenobenzol has been given bi-weekly, intravenously, in the arms. Following the earlier treatments there occurred a distinct reaction, namely, chills, fever, headache, nausea, and vomiting. The most constant symptom was a nervous chill lasting from ten to twenty minutes and appearing from ten to thirty minutes after treatment. Frequent urinalyses have shown only occasional traces of albumen in one case. After the injections there was some local reaction which readily yielded to the application of ice and massage. A summary of the cases shows that in one case the onset of the disease occurred ten days prior to admission to the hospital; in another case, fifteen days prior to admission, and in still another, one year. In the light of subsequent treatment, early diagnosis of general paresis, or at least of syphilitic involvement of the central nervous system, is of the utmost importance. Following treatment a definite clinical improvement has occurred in two of these patients. One patient has shown restiveness and a lack of cooperation to such an extent as to classify him as not improved. The definite results observed in the laboratory findings were: 1. The gold chloride test, although still positive, was much reduced in two cases. It was slightly increased in the case refusing treatment. 2. The albumen tests were reduced in all three cases from three pluses to one plus. 3. The globulin tests were slightly increased in one case; unchanged in the other two cases. 4. The cytological count was reduced in one case from 125 to 3 cells per c.c. There was a low normal count in both of the other cases. 5. The Wassermann reaction in the spinal fluid in one case changed from positive to unsatisfactory. In the other two cases it was unchanged, remaining positive. 6. The Wassermann reaction in the blood sera showed three negative and one doubtful reaction in one case; one unsatisfactory reaction in a second, and in the third case one unsatisfactory reaction and all the others positive.

1. **Tuberculosis in Relation to Feeblemindedness.**—Peter Bryce quotes from the observations of Tredgold and Goddard to bring out a fact frequently forced upon the attention of those who have had much to do with the tuberculous, and that is the relation of tuberculosis and what for the lack of a better term is called "nerve instability." He holds with Tredgold that primary amentia is a manifestation of a pathological germinal variation which has been produced by environment, and the germinal change is of the nature of a vitiation, that is to say, it consists of an impairment of the intrinsic potentiality for development, which may be widespread and affect the germ as a whole or which may be less extensive and confined to the neuronic determinant. This impairment is primarily due to the action of environment. Ancestral tuberculosis is but rarely the direct sole cause of amentia, but, like alcoholism, has an important indirect and possibly contributory influence. This indirect effect is seen in its potency to produce the milder and initial forms of nervous instability in the offspring, such as migraine, hysteria, and neurasthenia. The change in the mental and physical environment incident to the rapid urbanization of such a large proportion of the population of the United States and Canada during the past fifty years is the environmental condition that is largely responsible, operating against normal and physical causes. Among the other vices of civilization an irrational dietary and the use of foods of imperfect nutritive elements, due to the robbing of our common foods of their salts and vitamines, is not the least important. The effects of this changed environment on two generations are now becoming apparent and the question may be seriously asked whether phylogeny will disappear in its old normal developmental influences to be replaced by some modern man-created eugenics, adequate to cope with the changed environment, including habits of life, housing, occupation, and education. If by artificial methods we may greatly limit tuberculosis, the problem of feeblemindedness still remains to be attacked and will for an unknown period under modern conditions, give our legislators, educationists, clerics, and physicians ample occupation if they are to solve the problem satisfactorily.

2. **Some Thoughts on Prostatectomy.**—Henry H. Morton gives the results of their work at the Long Island College Hospital where, during the last three years, forty-three patients have been operated upon for hypertrophied prostate. The ages ranged from fifty-seven to eighty-two years. Of these forty-three patients, six died, two of the deaths being directly due to the operation, while the others were due to various other causes not dependent upon the operation. Thus the mortality rate for the series may be said to be 10 per cent. One should choose the route, supra-

pubic or perineal, which is best suited to the condition of the patient. The ideal anesthetic for old men is gas-oxygen with a little ether. Ether, if carefully given in small quantities, can also be safely used as an anesthetic. The after treatment of these cases is extremely important. The patient should be immediately put into a hot bed with an electric baker and the Murphy drip started at once. Water should be forced by the mouth as soon as the patient is able to swallow. The most dangerous symptom as a complication after prostatectomy is septic anuria. Its approach is heralded by the blowing up of the intestines, tympanites, dry brown tongue, scanty urine, and drowsiness. It demands the forcing of the water by the Murphy drip and by mouth. After suprapubic prostatectomy the writer uses silver wire sutures, which he leaves in. A big Freyer tube takes care of the clots. This is taken out on the fourth day. He also makes use of a rubber dam apron with a hole in the middle through which the urine runs out and is caught by gauze. This has proved a great comfort to the patients. He has found that incontinence of urine is more frequent after perineal section than after supropubic. As to the cause of death after operation, suppression of urine heads the list. Shock is rarely the occasion of death and hemorrhage ought never to cause death.

4. **Quartz Light in Cutaneous Diseases.** — Edward Pisko calls attention to the value of the Bach-Nagelschmidt modification of the Kromayer lamp in the treatment of cutaneous diseases. He says its use is indicated in all skin affections in which there is a dilatation of the blood vessels. He emphasizes, however, that the lamp's utlity is restricted to the treatment of small circumscribed lesions, such as are of an area no larger than the area through which the rays emerge. Conditions most amenable to treatment are furunculosis, folliculitis, acne vulgaris, and small patches of alopecia areata. Another group of skin diseases that can be influenced only by the deeper and more penetrating action of the rays includes lupus vulgaris, lupus erythematosus, naevus unius lateris, naevus vasculosus, naevus pigmentosus, and telangiectasis. The results obtained in the treatment of these cases have invariably been excellent, some times even startling. Gratifying results have also been obtained in cases of leg ulcer, intertriginous eczema, in a case of Duehring's disease, and in cases of obstinate and chronic eczema and psoriasis.

8. **A Test for Syphilis; Mercury Bichloride in the Blood Serum and Cerebrospinal Fluid.**—George B. Ubel bases this test upon the following facts: First, that bacteria react in accordance with all the established facts pertaining to colloids; secondly, one colloid may be absorbed by another colloid, preventing its precipitation when a mild precipitant is added. By assuming that normally there is a colloid present in the blood serum which is not present in the cerebrospinal fluid, the test may be satisfactorily explained. The addition of a 1 to 100 solution of mercury bichloride to the non-syphilitic blood serum will precipitate the colloid which is normally present, and a turbidity will result, but if the serum is syphilitic the colloid of *Spirochæta pallida* protects or absorbs the colloid normally present in the blood serum, and hence the serum remains clear when the precipitant is added. The reaction on the spinal fluid is just the reverse, that is, normally there is no colloid present, hence when the bichloride is added no precipitate is formed, but in a syphilitic spinal fluid the colloid of the spirachete is present and is precipitated by the solution. The technique is described and a series of cases tabulated which show that the results of this test are similar in most instances to those obtained by the other tests in common use.

10. **Recovery from Tetanus.**—B. Scheinkman reports a case of tetanus in which the administration of one dose of tetanus antitoxin of 6,000 units followed by three successive doses of 10,000 units failed to effect any change for the better in the condition of the patient. Five c.c. of a 2 per cent. carbolic solution were then injected and powders were prescribed consisting of quinine sulphate 2 grains, phenacetin, antipyrin, and caffeine citrate, each 1½ grains, and codiene 1/15 of a grain. These powders were given every two hours and the antitoxin discontinued. This treatment was continued for a period of two weeks, during which time the patient gradually recovered. Noteworthy features in this case were the facts that the patient's temperature never reached above 101° F., and only on a few occasions did the pulse show any erratic tendencies. The intellect remained unimpared throughout the entire attack.

6. **The Status of Physical Therapeutics in the Medical College Curriculum of To-Day.** — E. L. Eggleston says that it occurred to him that it would be interesting to know what attention was given to certain subjects in the medical schools of the United States, and the material he gathered forms the basis of his paper. He sent to each of the medical colleges listed and classified by the American Medical Association an inquiry as to the number of hours devoted to the presentation of the subjects of hydrotherapeutics, electrotherapeutics, mechanotherapeutics, massage, medical gymnastics, and dietetics. The replies to his inquiry indicated a decided interest in the subject. In summarizing the collected information, he finds that the average time devoted to the non-pharmacal subjects exclusive of psychotherapy was 62 hours, or about four times that recommended in the model curriculum. The majority of the schools were giving special courses in electrotherapeutics, a few considering the subject only in connection with other courses, such as neurology. Very few of the schools

were able to demonstrate the proper technique of the physical measures because of a lack of suitable equipment. The empiric use of hydrotherapeutic measures is fraught with grave danger in many cases of organic disease, and the same might be said with reference to massage and other physical measures, but this should not condemn them as of no value. When an individual has learned by experience of the fallibility of drugs, he has not infrequently lost confidence in his physician and has been led to employ as his advisor some one professing to cure physical ills without resorting to drugs. The number of such individuals has become so large as to provide a considerable field for the drugless healer. The day is past when the public is willing to be treated by medicines solely. Is it necessary that the patient be compelled to consult, in addition to the physician, a food expert and a gymnasium director to find out what to eat and how to exercise, or to consult an osteopath or a professional masseur to obtain the benefit from manual movements? It is high time that the physician be able to direct in all the activities having to do with the well-being of his patient, and that he so minister to all his physical needs that never again will the patient think of him as a dispenser of drugs only.

9. **Trichinosis.**—W. T. Cummins and G. R. Carson report of study of fifteen cases. The average incubation period was three weeks. One-third of the cases presented no orbital edema; three-quarters, no eruption; four-fifths, no bronchitis; none showed splenic enlargement. Eleven cases showed a disproportionately low pulse rate, to which little attention has been called. The maximum eosinophilia was 75 per cent. Of nine cases, eight showed trichinæ in the muscles; of the fifteen cases, none were found in the blood or feces; of twelve cases, one showed an embryo in the cerebrospinal fluid; of eleven cases, none were found in the urine; of fourteen cases, ten showed albumin in the urine. The mortality was 6.6 per cent. The fatal case presented a hypostatic pneumonia and a large pleural effusion. Evidently the parasites traverse the venous channels in very small numbers for mechanical reasons and probably none in some cases. It would appear that in many cases they suffer partial or complete disintegration in the intestinal tract. A routine spinal fluid examination may show that the nervous tissues are invaded in many instances; but it does not seem likely that this will serve as a useful diagnostic procedure in the study of the disease. If routine urinary examinations are made for parasites, it seems not improbable that invasion of this tract may be demonstrated.

2. **Observations of the Effect on the Addition of Fresh Human Blood Serum to Artificial Media.**—Leonard S. Dudgeon, F. Bawtree, and Dudley Corbett, in view of the fact that the ordinary media which are employed for the cultivation of bacteria outside of the tissues are not ideal, have tested the effect of the addition of human blood serum to various media. They find that this procedure has the following effects: 1. It provides a most favorable medium for growth where culture under artificial conditions may otherwise fail. 2. It greatly increases the amount of growth in those media to which it has been added compared to those prepared without it. 3. It stimulates the growth of pathogenic organisms as opposed to non-pathogenic. 4. It prolongs the life of organisms which are prone to die out under artificial conditions as shown in the case of the meningococcus. 5. It greatly facilitates the culture of the diphtheria bacillus, and in its combination with different media helps to illustrate all aspects of the morphology of this organism. 6. It exercises considerable influence upon other organisms of variable morphology tending in the case of the pneumococci to reproduce the true types as found in the body fluids. 7. It profoundly alters the fermentation reactions of the streptococci and pneumococci, tending to obliterate the finer differences between types or the differences due to particular environment.

4. **The Intravenous Injection of Oxygen Gas as a Therapeutic Measure.** — F. W. Tunnicliffe and G. F. Stebbing state that one of them (Tunnicliffe) has made it a practice for some time, when using saline venous injections, either simple nutrient or medicated, to use not simple saline solution but oxygenated saline solution. They have found that when pure oxygen gas is introduced into the veins of animals the latter do not necessarily succumb to gas embolism. More recent observations have been made on man, as a result of which it has been demonstrated that oxygen gas can be introduced into the veins in quantities from 500 to 1000 c.c. at the rate of 600 to 1200 c.c. per hour. Cyanosis and the dyspnea attending it are rapidly relieved. The more cyanosed the patient, the better is a rapid rate tolerated. As the cyanosis is reduced the rate should be diminished. During the administration the pulse should be watched and the heart auscultated frequently. Loud cardiac murmurs, more allied to stomach or intestinal rumbles in character than to ordinary heart murmurs, may, in fact often do, develop during the administration. These murmurs are not an indication to stop the administration, but with careful administration they need not occur at all. The phenomenon to be feared as likely to cause serious symptoms during the injection of oxygen is dilatation of the heart. The ideal case for reaping benefit from this treatment is one in which the cyanosis and dyspnea are due to respiratory difficulty and in which the heart is fairly healthy. In the opinion of the writers the method is not likely to be of benefit in the cyanosis and dyspnea occurring in marked degeneration of the myocardium. Under such conditions if gas injections are deemed advisable digitalin and strophanthin should be given first. The object of the authors is not primarily to point out conditions in which the injections of oxygen are suitable but to point out that this method is available to the clinician and will give therapeutic results.

5. **On the Gluteal Fold in Sciatic Neurits.**—Hildred Carlill calls attention to the obliteration of the gluteal fold in sciatic neuritis, and says it must depend on flexion of the thigh or upon some alteration in the condition of the underlying structures beneath the fold. In his cases there was no flexion of the thigh. In some cases Laségue's sign was also negative—that is to say the thigh could be flexed on the trunk, with the leg extended, without causing pain. When the sign is positive, from stretching of the nerve, it is a certain indication of a degree of affection in the nerve fibers or their sheath. The test is employed in the same manner as that employed in testing Kernig's sign in cases of meningitis, but the significance of the posi-

tive test differs in the two instances. It has been shown that Laségue's sign may be accompanied by momentary dilatation of the pupil, together with a raised blood pressure and an increased pulse rate. These signs occur in association with pain and serve to support a diagnosis of sciatica when malingering is suspected. Those patients with neuritis in whom the writer has found the fold absent, invariably had abolition of the ankle jerk. This is an important point in the diagnosis between neuritis on the one hand and pain, whether local or referred, in the distribution of the nerve, on the other. It is submitted that the condition of the gluteal fold may be of considerable diagnostic value in these cases, and may, indeed, be of great importance in those patients in whom it is not possible to test the ankle jerk. The absence of the gluteal fold in people with peripheral neuritis would go to prove that the whole length of the nerve is affected, including the roots of the sacral plexus.

6. A Case of Dilatation of the Hepatic Flexure of the Colon, Giving Rise to the Physical Signs Usually Associated with Subphrenic Pyopneumothorax. — W. J. Morrish reports this case, not only on account of the rarity of the condition, but also because of the importance of recognizing the possibility of its occurrence when deciding the question for or against laparotomy in any case in which the normal liver dulness is replaced by a resonant note, but in which other evidences of intraabdominal or intrathoracic suppuration are absent. The patient, a soldier 20 years of age, complained first of diarrhea and after three weeks jaundice came on. He became emaciated, had moderate pyrexia, and peripheral neuritis of the lower extremities. Over the right lower quadrant of the thorax, which was considerably bulged, the liver dullness was replaced by a tympanitic note. It was unlike pneumothorax and was certainly not a pulmonary cavity. An *x*-ray examination showed the ascending and transverse colon much distended with gas coinciding with the tympanitic area. A skiagraph taken after a bismuth meal showed that the hepatic flexure of the colon corresponded exactly to the tympanitic area marked out on the first examination. On making a median incision it was found that there was marked distention of the cecum and ascending colon to the middle of the transeverse colon. The cause of this was an extensive adhesion implicating the great omentum and passing from the great curvature of the stomach across the transverse colon to the duodenojejunal flexure. The portion of the great intestine distal to the adhesion was collapsed. The patient eventually died, and at the autopsy there was no evidence of ulceration or inflammatory thickening or abscess. The mucous membrane was atrophied and denuded of epithelium. There were similar changes in the small intestine. The condition was one of chronic enterocolitis. To find practically the whole of the liver dulness replaced by a tympanitic area giving rise to a well-marked coin percussion note, without either acute atrophy of the liver, transposition of viscera, or evidence of some inflammatory condition in the abdomen or thorax, is unusual.

1. Injuries of the Bladder and Urethra in War.—Andrew Fullerton finds from his experience that there are practically only two lines of treatment adopted for these injuries at the casualty clearing stations, namely, the tying in of a catheter or suprapubic cystotomy. Though these procedures have a definite place there seems to be a want of appreciation of the objects to be attained and the dangers attending their indiscriminate use. He emphasizes the value of aseptic urine in cleansing and irrigating a fistula, and in summing up expresses the opinion that suprapubic cystotomy is not necessary in many cases of wounds of the bladder, provided the latter can be kept clean and the external wound adequately drained. If there is likely to be much sloughing of the bladder walls, if there be severe and continuous primary or secondary hemorrhage, or if there be uncontrollable sepsis of the bladder, systotomy will be the correct treatment. Cystotomy is performed not so much for the benefit it will have on the original wound, which must be dealt with on ordinary surgical principles, but in order to drain a badly infected bladder and to prevent the spread of infection to the kidneys. In the treatment of wounds of the urethra, the usual method of treatment seems to be catheterization, and if that fails cystotomy. The performance of this operation is quite unnecessary, except perhaps in those rare cases in which blood finding its way back into the bladder forms large clots incapable of being evacuated. If the urethra is so damaged that either the patient is unable to void urine or is likely to have extravasation in attempting to do so, perineal section is performed. In all cases of doubt the same procedure is adopted. When one is unable to find the proximal end of the urethra except by poking around in the perineal wound a perineal section should be done, clots and tags removed, hemorrhage arrested, free vent for the urine provided, and the wound cleansed and left wide open. If then the patient is unable to pass urine, an aseptic puncture of the bladder in the suprapubic region should be resorted to till micturition is established through the perineum. Here the normal urine of the patient acts as an efficient cleansing lotion and flushes the wound.

3. Three Cases of Gastroptosis Treated by Gastropexy.—Middleton Connon records the history of three patients who were the subjects of well-marked gastroptosis. They were all males, not females as is commonly the case, and they were not neurasthenics—the usual type of patient in this disease. Occupation seemed to be a predisposing factor in each case, as they were all workmen who, over long periods, had, from the nature of their work, to lift heavy weights. Gastropexy, according to the method of Rovsing, was employed in all three cases. Great benefit has accrued from the operation after three years in one case, after one year in another, while in the third case the operation has been comparatively recent. Scott Riddell, in commenting on these cases, calls attention to the marked similarity of symptoms in cases of gastroptosis and gastrostasis from pyloric obstruction; to the marked assistance in diagnosis which may be obtained by means of the skiagraph after a bismuth meal, particularly by screening and skiagraphing in the erect position; the remarkable benefit which followed on the operation of gastropexy, and which appeared likely to be permanent, and the great ease and success with which Rovsing's operation can be performed as compared with Beyea's and other operations.

4. Perforation of a Gastric Ulcer Occurring in the Sac of a Large Congenital Diaphragmatic Hernia.—Lennox Gordon reports this case in which it was evident that there was an acute abdominal condition, but no satisfactory explanation of the lung signs could be arrived at. These consisted in a hyper-resonant note over an area extending from the costal margin as high as the lower border of the second rib; above this the percussion note became normal. Over this area of hyper-resonance the breath sounds were absent, but were present and normal at the apex. Posteriorly the hyper-resonant note extended from the costal margin to the seventh costal interspace, with deficient breath sounds over the same region. No moist sounds were heard in any area. The patient grew worse rapidly and died with signs of acute general peritoneal infection. At the autopsy it was found that half of the stomach passed up through a large opening in the diaphragm and occupied a high hernial sac extending into the pleural cavity, and that the perforation had occurred within the sac at the pyloric end of the stomach. Few reported cases of congenital diaphragmatic hernia have been diagnosed during life. The signs and symptoms which would make one suspect that such a hernia was present are: 1. Restricted respiratory movement on one side of the thorax. 2. A tympanitic note on percussion with breath sounds limited in some part of the thorax. If the bowels which occupy the hernial sac contain contents, then no tympanitic note may be obtained. 3. The heart is usually displaced, the displacement, of course, depending on the relationship of the heart to the ring of the hernia. 4. Signs of intestinal obstruction if strangulation of the hernia occurs. 5. Borborygmi may be heard on auscultating the tympanitic ring. 6. The most certain sign is that obtained from *x*-ray after a bismuth meal. The bismuth will show the position of the bowel above the level of the diaphragm. The first four of the above signs were present in this case. Another sign which in this case was of interest, and which may be of some diagnostic value, was the peculiar attitude the patient adopted. He stood, or sat up in bed, with the body bent well forward and the knees bent. This attitude appeared to be one which most relieved the tension of the diaphragm. The large contents of the sac and the large hernial ring (4 inches in diameter) made it evident that operation would have offered little hope of recovery. The hernial ring in this case was situated in the right anterior portion of the central tendon of the diaphragm in front of the liver, which is a rare position, and does not fall in with what we know of the development of the diaphragm.

Il Policlinico.

August 1, 1916.

Clinical Studies of Pernicious Anemia.—Roccavilla reports three cases of this affection. The first patient presented clinically the Biermer-Ehrlich syndrome. The second died eighty days after admission to the hospital, and the clinical diagnosis had been anemia perniciosa luetica, the Wassermann having been intensely positive throughout. Antiluetics could not prevail over the symptoms, and there was a positive intolerance toward mercury. The number of hemorrhages made any plan of intravenous medication difficult. There seems to have been nothing in the autopsy to suggest syphilis. In the third case the clinical diagnosis was anemia aplastica. All cases were hopeless from the start, and the author for personal reasons declined to make a trial of splenectomy. At autopsy lesions were found throughout nearly all the important organs, in part because of the generalized punctiform hemorrhages and transudations. Nephritis was a constant find and interstitial hepatitis with or without cirrhosis was present in all cases. Radical changes in the heart and great vessels were not of constant occurrence. The gastroenteric system generally suffered, and dryness of the mouth, throat and fauces is especially mentioned along with vomiting, anorexia and gastralgia. The finds in the blood, spleen and bone marrow are those to be expected in pernicious anemias.

Simulation of Typhoid Fever by Leucemia.—Bolaffi reports a case of subacute leucemia with small lymphocytoids, and another of chronic myeloid leucemia simulating typhoid fever. The last-named is of special interest, the author having been requested to make an autopsy on a victim of typhoid fever with bronchopneumonia. There seemed to have been no doubt as to the clinical diagnosis; the patient had high continued fever, diarrhea, abdominal meteorism, enlarged spleen, etc., along with the pulmonary complications. However, the widal had been negative, and blood cultures negative, although the latter find could not exclude typhoid. The liver was swollen greatly. Aside from numerous small hemorrhages and a general hypertrophy of viscerial and superficial lymphnodes, there had been nothing to cause suspicion of leucemia. However, a careful histological study of the visceria showed evidence of the myelocytic form of this disease. Was the syndrome of an infection due to some unknown complication, or was it a phase in the evolution of leucemia? The author holds to the second possibility.

El Siglo Médico.

August 5 and 12, 1916.

Hemopathies.—Pittaluga writes on the proper method of classifying diseases of the blood and introduces some innovations. For example, he recognizes a class which he terms hemodystrophies, which comprises hemorrhagic diathesis, polycythemia and chlorosis, Anemias (oligohemias) comprise the dysplasias (progressive pernicious anemia) and the orthoplastic forms. Eight forms of leucemia are enumerated. Under lymphoid hyperplasias, including splenomegalies, eight forms are also given. Under this group we find included the status lymphaticus. Here also belong the splenic anemias. Under granulomatoses we find the blood states of non-tuberculous scrofula and other conditions which simulate Hodgkin's disease, excluding all the leucemias. To a sixth group belong lymphosarcoma and congeners which are styled neoplastiform, in contrast with true neoplasms of the lymphatics. Blood parasites form a separate class, and from this the author naturally passes to bacteriemias, etc., closing with the blood states of non-infectious general diseases. The author discusses especially the dystrophies, as a new conception of blood pathology. Under hemorrhagic diatheses he includes all the acute, acquired forms, such as purpura, scorbutus, Barlow's disease, acquired hemophilia, Winckel's disease, paroxysmal hemoglobinuria and icterus hemolyticus, the two latter, however, belonging only partly in this group. Polycythemia is placed in the dystrophies because of its possibly neurotrophic character, as shown by the coexistence of vasoconstruction and vagotonia, and also by reason of the biochemical changes in the blood plasma. There can be no doubt that chlorosis is of dystrophic origin because of its nervous substratum, and endocrinic and metabolic factors.

Case of Encephalopathia Paludica.—Fernández Sanz relates the following case. Four years earlier, when patient was nine years old, she suffered from typical attacks of intermittent fever. These at the outset occurred daily for a week. At first diurnal the attacks

became nocturnal. There were in both cases periods of remission. At the period of highest temperature there was slight delirium. The child recovered spontaneously and exhibited some mental confusion and pareses, attributed to weakness. There had been no marked evidence of organic brain lesion. About three years later the fever reappeared, and on the ninth day, when temperature was highest, patient was seized with loss of consciousness and convulsions which became continuous (status epilepticus), and were followed by pareses of the face and extremities which slowly improved. When first seen by the author (*February*, 1916) she seemed in some ways remarkably well, but was seen to suffer from cough, tachycardia and tachypnea. The face was turned slightly to the right, and the innervation of the left side was inferior. There was weakness in some of the muscles of the extremities, and ataxic gait. The left half of the tongue showed paralysis, which was also notable in the left velum and left vocal cord. The tendon reflexes in all four limbs were exaggerated. Foot clonus was absent. Plantar reflex weakly positive with foot in plantar flexion. The patient probably had received some quinine during her last malarial attack, but exact data were lacking. A review of the case for its entire four years showed first the very insidious inception of nervous disorders dating from the periods of high temperature with delirium. The earliest nerve symptoms represented a left-sided paresis of the tongue, velum and larynx, and the isolation of these symptoms suggested a Jacksonian epilepsy, due to a bulbar lesion, perhaps a slight hemorrhage. The vagus was clearly implicated as shown by the behavior of the thoracic organs. This focal lesion was apparently the sole intracianial accident of the first attack. Three years later the nervous manifestations appeared suddenly as a convulsive crisis. The bilateral involvement of the muscles of the limbs suggested a second hemorrhage of unknown locality, producing temporary pressure symptoms, and capable of a considerable degree of recovery, in contrast with the Jacksonian lesion which left permanent consequences.

Radical Cure of Cancer of the Pylorus. — Panchet writes in the interest of gastrectomy with gastrojejunostomy (termino-lateral). The first pylorectomy was done by Pean in 1879. In 1895 Doyen published a full technique of the subject. The author has operated several hundred times by gastric resection. Cancer of the stomach is the most frequent of all cancers and 80% of it is pyloric. This location really has the advantage of giving the patient a much better chance for recovery under radical procedure. Precocious diagnosis may often be made by the combined aid of the *x*-ray and tubage followed by cytologic study. Exploratory laparotomy is practically without risk. It should be done, on a large scale, under local anesthesia and many cancers may be discovered in the early stage, and radically cured. Gastric chemistry is secondary in importance. Early operation means a benign operation. It is necessary that the four groups of gastric glands in association with the four vascular groups should be thoroughly extirpated, the vessels having been ligatured. The so-called benign operation need not last over 40 minutes; while for the more severe cases up to an hour and a quarter is required. The author is strongly opposed to two stage operations as favoring cancer grafts in the suture line in preliminary gastroenterostomy, while the secondary gastrectomy must be done within narrower limits and in general is rendered more difficult by the adhesions which result from the first stage. Again, many patients, once the gastroenterostomy is established, refuse to submit to gastrectomy; and a simple gastroenterostomy is indicated solely when metastases are present. It is seldom that exploratory laparotomy is contraindicated; this occurs in the main only in inoperable cases recognized to be such without its need (peritoneal metastases, adhesions to ribs, etc.). After the exploratory incision has been made, various conditions may be disclosed which render the cases inoperable, such as secondary nodules in the liver or peritoneum. In such cases, if there is pyloric obstruction in a small adherent stomach, jejunostomy should be performed; if there is no pyloric obstruction nothing should be done. If the case is operable save for hepatic and peritoneal metastases an anterior gastroenterosty (Y) or posterior gastroenterostomy should be performed according to location. If there are no metastases the case is radically operable. Gastrectomy may be simple or difficult according to circumstances. The former is the case in mobile pylorus. If numerous adhesions are present it is a question between pylorectomy and gastroenterostomy, and the majority of operators prefer the latter because of its low mortality, especially when done under local anesthesia. Other surgeons, like the author, prefer the added risk of a resection, because even if it be only palliative, the result is far better. Instead of a few months' survival we often get a year or more. The mortality from "mutilating gastrectomy" may vary from 4 to 30 per cent. On account of the short survival inevitable in gastroenterostomy the author would assume the 25% operative mortality risk in order to give a much longer survival to the others. Long survivals from gastroenterostomy are sometimes seen in chronic gastric ulcers which have finally become cancerous, but this is quite a special class of cases. The following rational signs aid in directing suspicion to a cancer: Loss of appetite and vigor, digestive disturbances not sufficient to account for the asthenia. Examination of stomach contents shows slight stasis and diminution of HCl. The *x*-ray examination shows either stasis or motor disturbance, thickened wall or a lacuna corresponding to the tumor. If cumulation of evidence justifies the step, exploratory lapurotomy is made. If a chronic ulcer is found which has not developed cancerous degeneration, it should be removed (71% of cancers are grafted upon ulcers). A simple resection of the pylorus may be regarded as a preventive of cancer. Before gastrectomy the patient should have his teeth scaled and gums painted with iodine, the colon evacuated and the stomach washed out with hydrogen peroxide. For 8 days before operation the patient drinks sterile drinks from sterile receptacles. He also practices respiratory gymnastics in the interest of prevention of post operative (hypostatic) pneumonia. Even in the most radical of operations the author does not use ether or chloroform anesthesia, but relies upon local or spinal analgesia with only brief inhalations of ethyl chloride. Gastrectomy is first done and the gastric stump at once implanted into the jejunum. The incision for resection is done with the thermocautery after previous use of the écraseur. The duodenum has previously been treated with the latter instrument and ligated, the stump being covered with a bit of omentum. At the close of the operation the patient is at once fed. Temperature and vomiting mean a clot of blood in the stomach and the latter should be irrigated with hydrogen peroxide solution until all washings come away clear. This condition may delay feeding, which consists of hot drinks, slightly alcoholized, followed after a few days with milk.

Insurance Medicine.

The Size of the Fee and the Value of the Examination.—Dr. C. L. McClellan says that the insurance companies should get what they pay for, although country practitioners unfortunately are not always prepared to give the companies what they should have for the money. Nevertheless, whenever the five dollar fee is cut down, the value of the examination is cut down. Instead of the fee being cut down, he would ask for an increase in certain cases. If an additional fee, say, only one dollar apiece, was given, when it was necessary to make a blood pressure test, then it would be some inducement for the country practitioner to buy a testing machine, for which he has little use outside of life insurance work. He further believes that if the insurance companies would insist on a tuberculin test in every case in which the policy was over five thousand dollars, or where the applicant was of tuberculous tendency, it would be inexpensive and it would be the best investment they could make.—*Texas State Journal of Medicine.*

The Full Duty of the Examiner.—Dr. H. C. Black says we make an examination of a man and find he is a good physical risk and we answer all our questions; have we done our full duty then? He was referee for a New York Company at one time and all examinations made in Texas came to him to see if there were any omissions, etc. An examination by a good reliable man came to Dr. Black with the statement, "this man is worthy of a ten-thousand dollar policy." Physically he was; he was a farmer and there was no doubt that he was in perfect health, but the writer happened to know him. He knew that when at home this man did not drink whisky, but every time he went to the city he would go down into the tough district of the town and stay there for weeks, drunk from the time he got there until he got home. Dr. Black wrote the facts to the company.—*Texas State Journal of Medicine.*

Life Insurance in the Tropics, Römer says, is profiting by the progress of recent years in tropical medicine. Life expectancy for officials in the Dutch East Indies is 5 years less, up to 35; 4 years less at 40; 2 years less at 50; while at 70 it averages the same as in the Netherlands. No statistics are available for non-officials. The intestines are in a condition of lessened resistance, the result of errors in diet, especially overloading with rice. The mortality among Europeans seems to be highest the third year of their residence in the tropics, then the fourth and fifth. On return to a temperate climate they are liable to pneumonia, and amebic dysentery may be responsible years later for an abscess in the brain or liver. Chronic malaria, sprue, heart disease and, especially, gout may reduce the life expectancy after return to Europe. An assumed simple cardialgia or gastritis may be the first manifestation of an ulcer or cancer. He urges that careful records be kept of persons who have returned from a residence in the tropics.

Tuberculosis runs a particularly malignant course in the tropics, attributed to the fact that the heart beat is accelerated on an average ten beats a minute and the respiration often by 4.5. Especially in the tropics, married men are better risks than the unmarried, as there is more attention to hygiene. Lands newly opened to colonization reduce the life expectancy somewhat. A tendency to corpulence is particularly risky in the tropics on account of the disinclination to exercise and the tendency to overeat.—*Nederlandsch Tijdschrift voor Geneeskunde,* January, 1916.

Life Insurance as a Specialty.—Dr. Irving McNeil says that there is a need for more careful selection of risks as shown by the mortality statistics: For instance, as Smith has brought out, quoting from figures given by W. R. Harrison, 60 per cent. of the deaths from tuberculosis in fraternal insurance companies occur within the first two years after being insured. Again, the statistics of the United States Government show a greater longevity among women than among men, yet the mortality tables of insurance companies show a lesser longevity. Why is this so? It is because women applying for insurance, as many do upon a premonition of their being something wrong, as a rule, are less carefully examined than are men.

But why, it may be asked, do life insurance companies accept examinations alike from the competent and incompetent, the careful and the careless, the painstaking and nonpainstaking examiners? It is because life insurance companies in spite of the large philanthropic element in their make up, are after all merely business organizations, like other business organizations and out for business and competition is so keen between the rival companies that they are inclined to forget some of the finer points and ideals. Whether in future the philanthropic element will get the better of the purely commercial, remains to be seen, but it is safe to predict that either on account of a lofty idealism or else because it will be found to pay in plain dollars and cents, life insurance companies will become more particular as to who makes their examinations and how and the physician who is properly equipped and who is willing to give his time and attention to this kind of work will find himself appreciated. A closer relationship between the medical director and his examiner should improve matters.—*Texas State Journal of Medicine.*

Metabolic Diseases in Relation to Obesity.—In a paper on the relation of disease to obesity, read before the Assurance Medical Society in London, Dr. F. Parkes Webber said that the not uncommon association of obesity with gout, uric acid gravel, and diabetes mellitus was so well recognized that there was no need to enter into any detailed discussion of the subject. Such associations could not seem surprising, if we remembered that obesity itself, whether inherited or acquired, was a metabolic disease or a metabolic abnormality. Moreover, over-eating and sedentary habits were certainly not rarely factors in the causation of gout and diabetes mellitus, as they were in the causation of obesity. It was especially the mild form of diabetes mellitus occurring in middle-aged and elderly persons that was associated with obesity.

The Relation of the Medical Examiner to the Medical Director.—Dr. M. B. Grace criticises somewhat severely the attitude frequently assumed by the medical directors of insurance companies to their medical examiners. However, Dr. Grace says this attitude of the medical director is undergoing a rapid change for the better and he believes that the time is not far distant when both eyes of the medical directors will be wide open and their sensitive appreciation of honest work carefully executed will reduce them to reward instead of castigating medical examiners for their work.—*Texas Journal of Medicine.*

Book Reviews.

TUBERCULOSIS, A PREVENTABLE AND CURABLE DISEASE; Modern Methods for the Solution of the Tuberculosis Problem. By S. ADOLPHUS KNOPF, M.D. (New York and Paris), Professor of Medicine, Department of Phthisiotherapy, at the New York Post-Graduate Medical School and Hospital. New Edition. Octavo; 394 pages, with 115 illustrations. Price, $2.00 net. New York: Moffat, Yard & Co., 1916.

THIS book comes from one whose authority on the subject is so unquestioned that his unwavering optimism is like a call to victory for the race. Dr. Knopf is far from minimizing one iota of the dread details of this frightful scourge; he knows it from its insidious beginnings to its fatal end, but his whole book is written to show that it need have no beginning, or, if too late for that, that it may be balked of its end; in short, it is both preventable and curable. The author's style is of the clearest; it would be as impossible for the plain man to misunderstand him as for the literary to fail to enjoy him. He frankly gives to the public all necessary data. . . . Dr. Knopf outlines with a vivid clarity all his own the duty of every member of the community in this crusade, and ends in a note of splendid optimism that, coming for such a source, may well put heart and hope into the most fearful.

We have repeated here what was said in our review of the first edition of this work. The reviewer has nothing to add in reference to the new edition, except to state that in it many of the typographical and some historical errors of the first edition have been corrected and a chapter which might be called a reply to the criticisms on the first edition, with comments by prominent authors, has been added. If anything, this should make the new edition even more interesting than the first. For those who are not familiar with the former edition we reproduce the titles of the twelve principal chapters, which speak for themselves: What a Tuberculosis Patient Should Know of His Disease; What Those Living With Patients Should Know Concerning the Disease; The Duties of the Physician Toward His Patient, the Family of the Patient, the Community He Lives in, and Other Communities; How the Sanatorium Treatment May Be Adapted to and Imitated in the Home of the Consumptive; How Sanitation and Proper Housing May Help Toward the Prevention of Tuberculosis; The Duties of Modern Municipal Health Authorities; The Duties of State and Federal Authorities in the Combat of Tuberculosis; What Employers, of Every Kind, Can Do to Diminish Tuberculosis Among the Men and Women Working for Them; The Duties of School Teachers, Educators in General, and of the Public Press in the Combat of Tuberculosis; The Duties of the Clergy, Philanthropists, Charitable Individuals, and Charity Organizations; The Duties of the People in the Combat of Tuberculosis; Prospect of Ultimate Eradication of Tuberculosis.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, etc. Edited by H. R. M. Landis, M.D. Volume II. Twenty-sixth Series, 1916. Price $2. Philadelphia and London: J. B. Lippincott Company.

IN this issue of the Clinics there are twenty-four articles of treatment, medicine, psychiatry, obstetrics, public health and surgery. The subjects range from a timely article on venesection and its indications by Beardsley through interesting discussions of auricular fibrillation by Canby Robinson and immobility of the diaphragm by Pryor to the first portion of an extensive analysis of fifty cases of dysthyroidism by Swan. Other articles on varied topics help to make this number one of the more interesting and instructive issues of the International Clinics.

THE KINETIC DRIVE, Its Phenomena and Control. By GEORGE W. CRILE, M.D., Professor of Surgery, Western Reserve University; Visiting Surgeon to the Lakeside Hospital, Cleveland. Wesley M. Carpenter Lecture, 1915. Edited by AMY F. ROWLAND B.S. Price, $2 net. Philadelphia and London: W. B. Saunders Company, 1916.

To those who are familiar with the writings of Dr. Crile upon this subject this small book will bring nothing especially new. It is in effect an epitome of his larger work "Man—An Adaptive Mechanism," such as could be presented in a single lecture and embodies the same ideas and suggestions, put forward in the author's always interesting and attention-compelling style. The book makes a handsome appearance but is quite small.

STUDIES IN ETHICS FOR NURSES. By CHARLOTTE A. AIKENS, formerly Superintendent of Columbia Hospital, Pittsburgh, and of the Iowa Methodist Hospital, Des Moines; formerly Director of Sibley Memorial Hospital, Washington, D. C. Price, $1.75. Philadelphia and London: W. B. Saunders Company, 1916.

THE author of this work is well known as a writer of books for nurses; the present volume is probably the most useful of the set. The author has evidently observed carefully and pondered deeply over the many factors which enter into the life and success of nurses. In this volume will be found a discussion of such topics as Loyalty, Responsibility, Habits, Temper, Truthfulness, Obedience, Economy, Tact, Hospital Accidents, Honesty in Bedside Records, Response to Calls, Picking Cases, Too Much Dignity, The Nurse Who "Tells Things." The book is well and brightly written and is well worth reading. Many a patient can indorse what the author has to say about "preventable noises," the "hospital manner," and the nurse "with a commanding presence." There is much in the book which should make readers stop and think; and the result will be appreciated by doctors and patients.

REFRACTION OF THE HUMAN EYE AND METHODS OF ESTIMATING THE REACTION, Including a Section on the Fitting of Spectacles and Eyeglasses, etc. By JAMES THORINGTON, A.M., M.D., Emeritus Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine; Member of the American Ophthalmological Society; Fellow of the College of Physicians of Philadelphia, etc. Price, $2.50. Philadelphia: P. Blakiston's Son & Co., 1916.

THE author's preface gives an excellent idea of the aims and scope of the book. It is to teach the student the necessary physics and mathematics for an understanding of his subject, and then give him the methods by which refractive errors may be found, analyzed, and corrected. It is an excellent book for beginners, because it is written with unusual clearness, gives necessary details as to technique, and yet is not overburdened with mathematics. The organization of the book is good, leading from detail to detail of the study and work logically and clearly in spite of the marked condensation necessary to cover a large subject in 400 pages.

A MANUAL OF GYNÆCOLOGY AND PELVIC SURGERY FOR STUDENTS AND PRACTITIONERS. By ROLAND E. SKEEL, A.M., M.S., M.D., Associate Clinical Professor of Gynæcology, Medical School of Western Reserve University; Visiting Surgeon and Gynæcologist to St. Luke's Hospital, Cleveland; Fellow of American Association of Obstetricians and Gynæcologists; Fellow of American College of Surgeons. With 289 illustrations. Price, $3.00. Philadelphia: P. Blakiston's Son & Co., 1916.

DR. SKEEL'S book adds one to the present list of good texts in gynecology. It is a convenient size and the type is good. The illustrations are numerous, clear, and well chosen. Operative technique is adequately illustrated and explained, and diagnosis is carefully covered. The book, as Dr. Skeel planned, is a satisfactory one to put into the hands of student or practitioner. The discussion of "Treatment of Menstrual Disorders" is brief and unsatisfactory. No mention is made of the value of exercise, both intermenstrual and at the onset of pain, nor of the value of belladonna in the spasmodic type of dysmenorrhea.

THE MEDICAL CLINICS OF CHICAGO, March, 1916. Volume I, No. 5. Price $8 per year. Published bimonthly. Philadelphia and London: W. B. Saunders Company.

THIS number contains eighteen case presentations from seven different clinics and follows the style of the previous numbers. The cases are given a little more space than in some of the previous numbers which is a decided improvement. The best contribution is the discussion of congenital syphilis by Abt. One good feature of this issue is the subsequent report of two cases previously presented. This is a good thing, but one cannot help feeling that the report would be a little more instructive if it had been withheld until the whole case could be presented at once. The serial method lacks impressiveness.

Society Reports.

AMERICAN THERAPEUTIC SOCIETY.

Seventeenth Annual Meeting, Held at Detroit, June 9 and 10, 1916.

THE PRESIDENT, DR. ROBERT T. MORRIS, NEW YORK CITY, IN THE CHAIR

President's Address. — Dr. MORRIS stated that in the midst of rapid advancement in special studies he would ask the question whether the physician to-day really cared to know what was the matter with a patient, or did he prefer to find in the case something in which he was very much interested. A concrete example was diabetes mellitus, which was only a symptom. Did the physician attend to make a diagnosis of diabetes as a diagnostic entity? No; it was a signal or sign to him, and he now proceeded to find out what was the matter with the patient. He knew that diabetes mellitus was always due to hyperglycemia. He knew that some peripheral irritation or some focal infection might be exciting the adrenals, which in turn excited the whole thyroid, the chromaffin system, the liver, causing disturbances of function, so that in considering diabetes from a therapeutic standpoint one should begin with the question of what peripheral irritation or what focal infection might be driving the adrenals up to the point where there was cough as a symptom of diabetes mellitus. If one did not do this and was interested only in the symptoms, the patient as a whole was left out. In the rapid advance of laboratory methods one man did not know what another man was doing. This was true not only in medicine but in chemistry. The layman in trying to select a competent medical adviser to-day was very much like a client in a court of law trying his own case. The time was coming when we should have a new kind of consultant, one who took the word of the analyist, applied the lines of his synthetic mind, and brought together parallel rays in such a way as to focus them upon the case as a whole. When we had the new ideas of Lane with regard to colonic infections presented to us, we all became intensely interested, and it was soon found that Lane had struck the germ of a great truth; but something was behind the colon or the enteron causing functional disturbance, and if one merely took out the red flag he did not try to determine what the red flag stood for. If he took a lot of cases of gastric ulcer and of goiter that were sent to him for operation, the patients having decided that an operation was the thing to be done, he found by putting them through the laboratory and making a careful study of their cases they were not surgical cases at all. He had found this over and over again. He doubted if he operated upon one-half of the patients who were sent to him for operation at the present time. We were dealing with very deep questions when we were working out those of peripheral irritation and focal infection, and the patient should be considered from every point of view.

What Therapy Means.—Dr. OLIVER T. OSBORNE of New Haven, Conn., stated that practitioners should not forget to use every means to prevent the spread of contagion and the infection of others, if the disease was contagious. If the disease was not contagious, the general hygiene and care of the secretions of the nose and mouth and of the excreta were always of more or less importance. If the cause of a disease could be removed or actively combated, that was the part of the treatment that took precedence of all others. If the disease, or its localization, or its lesion, or a simple condition, as a cold or a headache, could be aborted, that was another primary object of treatment. The direct treatment of the cause might do this or local measures, as ice, heat, hyperemia, leeches, purges, simple surgical measures, or various drugs might so act as to prevent, control, or abort an impending lesion of functional disturbance. A lesion having occurred, the patient would not be well until it had disappeared, resolved, or been removed, and hence as soon as a lesion had been established, it was the aim of all of our science to eradicate it. Time and nature's own antagonistic and recuperative powers might unaided accomplish this object, but very frequently we could aid and hasten nature's processes by various means. Frequently, only surgery could remove a lesion. At other times a lesion became permanent and the patient was permanently damaged to that extent. He might be apparently well in spite of this defect, or he might be well as long as he modified his food, life, and activities; or he might be an invalid; or the lesion might be the cause of his death sooner or later. However, in any of these eventualities the treatment or management of the lesion and its pathological results was the main object of treatment. Whether or not the lesion could be successfully treated, objectionable or disturbing symptoms must be stopped or ameliorated. Students were not sufficiently taught, and the practitioner did not often enough consider the disturbances of function due to or caused by the disease that was present. The diet must of necessity be modified by the intensity of the illness, the character of the illness, and the condition of the organs of digestion. The food and drink must always be carefully considered, regulated from day to day to meet the conditions and then gradually increased during convalescence, or perhaps be modified by a lesion that was permanent.

Dr. FRANCIS M. POTTENGER of Monrovia, Cal., stated that one should not only consider the lung, the heart, the stomach and intestinal tract, but the nervous system in dealing with cases that presented themselves. Modern medicine centered its attention largely on scientific facts and forget the fact that the patient was not a thinking being, and in so far as this fact was forgotten did the practitioner fail. The idea of the essayist was broad and he was following out the best of what modern therapeutics stood for.

The Relationship Between the Nervous System and Therapy in Pulmonary Tuberculosis.—Dr. FRANCIS M. POTTENGER of Monrovia, Cal., said there were several facts which led him to believe that the more important factor in the production of temperature was an interference with normal heat dissipation, rather than an unusually active heat production. In support of this theory he offered the following facts: (1) The experimental introduction of protein produced a general sympathetic stimulation. (2) The manifestations of clinical toxemia were those of general sympathetic stimulation. (3) It had been noted on experimental animals that when protein was injected parenterally that there was a constriction of the vasomotors of the surface, as determined by the constriction of the vessels of the ear of the rabbit (Jona). (4) A rise of temperature was accompanied by other symptoms of toxemia, and was accompanied by constriction of the superficial blood vessels, which, at times, manifested itself by a sensation of chilliness. (5) The action of toxins and adrenin was practically the same; both acted chiefly upon the nervous system. The introduction of adrenin caused a constriction of the superficial blood vessels, and a rise in body heat. From these facts he was led to believe that the rise in temperature which occurred in natural infections, or whenever a foreign protein of any type was introduced parenterally into the body of either man or animal, would not occur apart from their action through the sympathetic nervous system, which produced a general vasoconstriction of the superficial blood vessels, and interfered with the dissipation of heat. He was further convinced of this from the fact that emotional states, particularly the depressive emotions, such as those of fear, disappointment, anxiety, discontent, and worry, produced a general sympathetic stimulation; and that all of these depressive conditions were associated with a rise in temperature, at least in the tuberculous individual. Since sympathetic stimulation was produced by toxins, no matter what their source, we might find it in tuberculosis as a result of the absorption of protein from the bacillus itself, probably also as a result of the absorption of destroyed tissue and from any other bacteria that might complicate the process. While toxemia could not be caused by the depressive emotional states, yet these produced sympathetic stimulation and acted in the same manner as toxins; consequently, they must also be relieved the same as toxemia, if we would relieve the organisms from the inhibiting action of the sympathetic system.

Rest was an essential in treating toxemia. It was valuable whenever exercise increased the sympathetic stimulation by pouring forth into the tissues an increased amount of toxins. Thus we note that patients with rapid heart's action, poor appetite, deficient digestive activity, constipation and rise of temperature might experience an improvement, or even lose all of these symptoms under rest; and, as they disappeared, encouragement followed and a general improvement took place.

The influence of *food* might be greatly enhanced by relieving the sympathetic stimulation due to toxemia and depression. He usually noted that the appetite and digestion, and, therefore, nutrition of the patient improved when he was put at rest in the open air and given hope and encouragement.

There was a time when *exercise* had an important and beneficial influence upon the patient. Exercise called for increased metabolism. Increased metabolism was met by increased food intake; consequently, after toxemia had passed and the patient could exercise without producing toxic symptoms we could greatly improve his nutrition by permitting exercise.

The effect of *baths*, either air, sun, or water baths, was exerted through the nerve endings in the skin and extended to every cell of the body. If the reactivity of the skin was well cared for, as it might be through the stimulating effect of water, light, or air, upon it, the vasomotor tone was improved, the metabolic activity of the patient's cells was hastened, and the elimination of heat, moisture, and various toxic products was hastened.

Dr. Ernest Zueblin of Baltimore, Md., was gratified that Dr. Pottenger had discussed the problem of therapeutics and of therapy in general on such a broad basis. In connection with the therapy of tuberculosis and varied manifestations of the disease the sympathetic nervous system played an important rôle. From personal study and observation, the speaker had found that in most infections the sympathetic nervous system was deranged. A very interesting fact was that the rise of temperature in cases of tuberculosis could be explained by the retention of heat. We could explain certain psychogenic causes in connection with the rise of temperature by the existence of toxemia and disturbed action of the sympathetic nervous system. It was known how the gastrointestinal tract was affected under the influence of disturbed reaction of the sympathetic nervous system.

Dr. Oliver Thomas Osborne of New Haven thought the time had passed when we should have a series of books on the practice of medicine or anything else when treating disease of this or that particular type. We should simply consider that we had types of infection, and with specialization that particular view should be held. Headache, backache, fever, dry tongue, nausea and vomiting were all symptoms of infection. The treatment of the condition depended on what the future prognosis was and how actively the patient was treated.

Oxygenated Milk.—Dr. Clifford G. Grulee of Chicago read a paper on this subject and drew the following conclusions: "(1) It would seem from our experience that oxygenated milk has a definite place in hospital régime. It offers us the safest milk from all standpoints at a very much lower expense than that at which certified milk—with which it compares very favorably—can be obtained (about six cents to the quart). (2) There is always fresh milk to be had, a great advantage to a diet nurse who is rushed for time. (3) All danger of infection from pathogenic organisms present in the milk is removed. (4) There is no danger to the infants from sour milk which contains no specific pathogenic microorganisms, whatever this danger may be." As to whether it would be possible to market this milk on a large scale or whether this would be desirable, he was not willing to put himself on record. Certain things had led him to think that this could be done and possibly to advantage. That it had worked out to entire satisfaction in the Presbyterian Hospital of Chicago he had no hesitation in asserting.

Dr. Francis M. Pottenger asked Dr. Grulee what was the process of aeration.

Dr. Grulee replied that the milk was heated to 122-128° F. for one half hour, and was stirred by a fan in the reservoir so that it was kept in motion the whole time.

Dr. Noble P. Barnes of Washington, D. C., asked Dr. Grulee if he found that the natural enzymes were destroyed by this process, or whether the lactic acid bacillus was killed from prolonged heating in these cases, as was sometimes observed in feeding sterilized or pateurized milk.

Dr. Grulee in speaking of whether there was killing of the lactic acid bacillus in the milk, stated he had not observed any harm from it. This milk was being used with increasing frequency in the hospital, and some of the men in the internal medical service thought that this milk was better in feeding typhoid cases than ordinary milk. They got the milk in ten gallon tanks from the farm and it cost five cents a quart.

Dr. Robert T. Morris asked as to the effect of sterilized milk when given to babies.

Dr. Grulee replied that he could not answer the question satisfactorily, but he had always felt that the danger of sterilized milk given to babies had been exaggerated. He happened to know of only one case of scurvy which occurred in the practice of a colleague who gave the child raw milk. He then boiled the milk, gave it to the child, and the scurvy cleared up.

The Therapeutics of Cerium. — Dr. Reynold Webb Wilcox of New York said we could safely assert that cerium oxalate resembled bismuth subnitrate in its therapeutic action, with the advantage that it did not give rise to such an unpleasant odor to the breath as did the latter, owing to the tellurium contained in it, and that it was not so likely to be contaminated with arsenic as was the latter. The therapeutic uses of cerium oxalate were very similar to those of bismuth, which were for local effect, and success required that the doses should be of a magnitude commensurate with the results which it was desired to obtain, namely, 10 grains every four hours. Further than this, this dose should be frequently exceeded, as it was known that it could be done with safety, 30 grains having been administered with good results. Bearing these facts in mind, the results of twelve years' experience in the use of this remedy had been confirmed by skillful therapeutists in internal medicine, and had shown conclusively that cerium oxalate was an agent which, when used in proper dosage and with due discretion, would produce typical and satisfactory results, and its therapeutic value could not be disputed.

Experimental Pathology of Goiter.—Dr. Ernest Zueblin of Baltimore called attention to the point that Kocher had already reached the conclusion that goiter must have a certain etiological relation to certain admixtures and impurities of the soil, which must be of an organic or organized nature, of a short lifetime, since the disease only increased as long as the suspected water was used. Wilms, based upon the experiments of Bircher, expressed the following theory: He admitted as the cause of goiter a toxic substance not of parasitic nature but containing the dried animal residues found in the geological layers characteristic for the periods of marine submersion. The water passing through these layers became polluted by these substances and became goitrogenous. Heredity and disposition played no doubt a rôle in endemic cases of goiter, while changes in the internal secretion must be thought of, particularly in cases of sporadic, to a lesser extent in instances of endemic, goiter. The suprarenal bodies, ovaries, pancreas, etc., no doubt influenced each other in their functions and a diseased condition of these organs must have a disturbing influence upon the general functional equilibrium. As regards the influence of heredity, opinions differed considerably. The general impression gained from the present knowledge of the goiter problem was, that we had not yet reached a satisfactory understanding of the etiological factors. Further contributions studying the possible influence of geological strata, of colloid substances, the water supply, the influences of altered internal secretion, and of other possibilities upon the production of goiter would certainly help our understanding of the complex goiter problem.

Suggestions for Locating Focal Points of Infection.—Dr. Noble P. Barnes of Washington, D. C., pointed out that beginning with the introduction of bacterial vaccines, when Koch recommended and used tuberculin, practitioners witnessed one reaction after another and had failed to take advantage of one very important practical application. Koch's tuberculin treatment was then a failure because of misapplication. Time after time was a focal smouldering ember fanned into an active and destructive inflammation because of an overdose of tuberculin. This focal reaction had presented itself in most every injection he had carefully observed. The flaring up of a boil or carbuncle after administering a suitable vaccine, the appearance of urethral discharge, frequent urination, or strangury, after using gonorrheal vaccine, and the bursting forth of embryo pimples after injection of acne vaccine were common observations. Having these facts in mind, after prolonged treatment of a case of gonorrheal arthritis with prostatic massage, irrigation, and carefully measured doses of vaccine, in which there were days of encouragement, although the end result was nil, the author decided to give the patient an unusual dose of the vaccine and thus incite an intense reaction in the joints

from which he always experienced a marked improvement. Within twenty-four hours his patient had a temperature of 103.5° F. with all the symptoms of a general infection. Pain in the affected parts was severe. Interesting and suggestive was the stimulation of an unsuspected focal point of infection resulting in a most distressing epididymitis. The patient informed the author at this time of a similar inflammation of the same structure during one of his outbreaks of unpleasantness over twenty years ago. Here then was a focal point of infection he had overlooked. Upon this suggestion of locating focal points of infection by obtaining a reaction following a larger than the therapeutic dose of vaccine, he had been working with a number of cases. Focal reactions were caused best, if not only, by injection of the killed infecting microorganisms, and, as some of these organisms had a wide range of affinity and adaptability, the selection of the vaccine was very important. Vaccines and serums prepared with due regard for tropic conditions would be the requirements of the future and no doubt many of the failures to-day would be successes to-morrow.

The Means of Prevention and Retardation of Cardiovascular Disease.—Dr. CHARLES LYMAN GREENE of St. Paul, Minn., drew the following conclusions: (1) It has now become possible measurably to retard and, to a considerable degree, prevent cardiovascular diseases. (2) That it is imperatively necessary in the interests of the cardiopath and of the race that a justifiable optimism should replace the almost universal pessimism now existing. (3) A knowledge of the specific bacterial origin of diseases of the heart should be promulgated together with the means best adapted to control of causative conditions. (4) Our old ideas with relation to cardiac dimensions should be radically revised and brought into correspondence with the actual facts as at present definitely established. (5) Modern methods of percussion, accurate and definitive, should replace the older practice still in vogue. (6) The cardinal value and importance together with the nature and diversity of subjective symptoms of cardiac inefficiency should be given their full value as means of early diagnosis and indicators for therapeutic initiative. (7) The extraordinary usefulness of test doses of digitalis with or without reinforcement by physical rest constitute the very foundation of timely diagnosis. (8) A thorough understanding of the anatomic peculiarities of the drop heart, its association with a definite constitutional state, its remarkable prolificacy with respect to the production of symptoms of a most varied and obscure character, together with the misleading narrow diameters present even in dilatation, making the condition one of great clinical importance. (9) The common occurrence of the drop heart, its constant relationship to general visceroptosis of which it is a part, its frequent association with so-called nervous dyspepsia, and the almost universal tendency to lose sight of the true cause of its symptoms by referring them to the bastard symptom conglomerate long known as "neurasthenia" are facts of decided clinical importance. (10) The existence of the drop heart in the male is a matter of great importance with respect to the fitness of its possessor for hard manual labor and actual service in warfare. (11) An application of such of the newer discoveries in the cardiovascular field as are here enumerated cannot fail to exercise a striking effect both with relation to the prevention of cardiovascular disease and the retardation of established cases."

Notes on the Blood and Its Vessels in Epilepsy, and Their Treatment.—Dr. THOMAS E. SATTERTHWAITE of New York contributed a paper on this subject, in which he gave a brief survey of the relation of cardiovascular phenomena to epilepsy, and then drew the following conclusions: "(1) Abnormalities of cardiovascular phenomena occur in the vast majority of epileptic seizures. (2) The grosser forms of cardiac disease occur rarely in epilepsy. In fact, they are present in so small a proportion as to indicate that they are accidental incidents rather than determining factors of it. (3) That a cerebral disease or abnormality may produce epilepsy is well established. The evidence of it has been that removal of enlarged veins or nevoid growths adjacent to the base of the skull has been followed by cessation of the seizure. (4) There is, therefore, a reciprocal relation between circualtory disorders and epilepsy to this extent: that epilepsy causes circulatory disturbances and that abnormalities of blood or vesse'ls cause epilepsy. This reciprocal relation I believe to have been overlooked hitherto. (5) In most forms of epilepsy there is cerebral anemia, and this is relieved effectively by various heart stimulants, the high frequency current, and radiant electric light. The importance of the use of cardiac stimulants in epilepsy I believe has not been properly appreciated by the profession at large. In a certain number of cases, of course, permanent relief is obtained only by antiluetic treatment or some surgical procedure."

Mercurialized Serums.—Dr. F. E. STEWART of Philadelphia drew the following conclusions: "(1) Corrosive sublimate becomes non-corrosive and non-irritating when dissolved in normal serum. (2) The compounds thus formed are just as toxic and probably therapeutically as efficacious as mercuric bichloride itself. (3) When prepared from heterologous serums, mercurialized, serums must be regarded as heterologous serum preparations, requiring conformity to the same rlues in their administration as applied to other heterologous serums, such as diphtheria antitoxin, and antibacterial serums. (4) Mercury in the form of mercurialized serums is an ideal form for administering mercury subcutaneously, intramuscularly, intravenously, and intraspinally. (5) Subcutaneous and intramuscular administration are the methods of choice. Intravenous and intraspinal administration should be the methods of resort only when especially indicated, as outlined in the publications of Dr. Byrne and Dr. Thompson, who have made a special study of the subject, and whose papers in contribution to this symposium will inform you in regard to their use."

The Comparative Toxicity of Mercurialized Serum and Bichloride of Mercury When Injected Intramuscularly, Intravenously, and Intraspinally.—Dr. PAUL S. PITTENGER of Philadelphia drew the following conclusions: (1) Mercurialized serum whether injected intramuscularly, intravenously, or intraspinally, is equally as toxic as corresponding amounts of plain bichloride of mercury. (2) The addition of an excess of serum to bichloride of mercury does not reduce its toxic properties but merely deprives it of the property of destroying tissue by precipitating and then dissolving the albumin of the tissue, without changing its toxicity or therapeutic efficiency. (3) Intramuscular or subcutaneous injections of mercurialized serum are practically painless and are not followed by sensitiveness, pain and sloughing which usually accompany injections of the plain bichloride. (4) Intravenous injections of mercurialized serum are not followed by pain or sensitiveness at the site of injection. (5) Overdoses of mercurialized serum when administered intravenously produce the same untoward effects, such as blood in the stools, vomiting, retching marked increased and troubled respiration, etc., as plain bichloride of mercury and care should be used, therefore, not to produce toxic effects by overdosage or administration at too frequent intervals. (6) Mercurialized serum in proper doses may be safely injected directly into the spinal canal. (7) In systemic syphilis very favorable results can be obtained by the intramuscular or subcutaneous injection of mercurialized serum. (8) Intramuscular or subcutaneous administration of mercurialized serum is to be preferred in the treatment of systemic syphilis except in patients where quick results are imperative in which case the serum may be administered intravenously."

Mercurialized Serums.—Dr. LLOYD O. THOMPSON of Hot Springs, Ark., said that upon reading Byrnes' original article upon the intradural injection of mercurialized serum in syphilis of the central nervous system the thought suggested itself to him that if mercurialized serum could be injected intradurally without irritation, it could be infected intravenously without causing phlebitis. He had tried it with perfect success and in May, 1915, reported 66 injections in 8 cases. The method of procedure was as follows: From 40 to 50 c.c. of blood were collected by venepuncture and placed in a large test tube which had been boiled in salt solution. After separation the serum was poured off and thoroughly centrifugalized. A watery solution of mercuric chloride was prepared so that each cubic centimeter contained 22 mg. (1/3 grain) of the salt. The serum was then measured and divided into two parts, one-third of the amount placed in one tube and the remainder in another. The mercury solution was added to the first part in the proportion of 1 c.c. to each 2 c.c. of the serum. A heavy precipitate of albuminate of mercury appeared which was completely dissolved on the addition of the remainder of the serum. It would be seen that the mixture would contain 22 mg. (1/3 grain) of mercuric chloride in each 7 c.c. At first there was great difficulty encountered in keep-

ing the albuminate in solution for any length of time, and it was necessary to prepare the solution fresh before each injection, but later it was discovered that if the mixture was heated in the water bath for one-half hour at 55°C. it would remain in solution indefinitely. Mercurialized serum for intravenous injection prepared from horse serum had been placed upon the market, but owing to the danger of anaphylaxis he had not employed this serum and did not recommend its use. Recently, he had used ascitic and hydrocele fluids in the preparation of mercurialized serum for intravenous injection with very favorable results. These fluids, however, varied somewhat in their ability to hold the mercury albuminate in solution, some of them requiring as much as 10 c.c. to each 22 mg. (⅓ grain) of the bichloride. It had occurred to him that the use of these fluids might present an opportunity for placing mercurialized serums upon the market from the use of which there would be no danger of anaphylaxis. It might be well to state parenthetically that ascitic and hydrocele fluids should be tested for the presence of tubercle bacilli before using for intravenous injections. He had not used mercurialized serum intravenously as a routine procedure in the treatment of syphilis but had used it mainly in those cases in which the pain of intramuscular injection was so great that the patient would not tolerate them.

Head Colds; Their Results and Treatment.—Dr. THOMAS F. REILLY of New York in a paper on this subject emphasized the following conclusions: (1) That there was a special type of head cold that preceded by from four to eight days most, if not all, cases of so-called muscular rheumatism, lumbago, etc., and that this was more satisfactorily treated by treating the original site of infection in the nose than by the usual methods of treatment. (2) That bronchitis following such head colds was likewise more satisfactorily treated by taking care of the original source of infection in the nose. (3) That this field of nasal treatment was quite as much the province of the internist as the use of the stomach pump in gastric lavage. (4) That a fair proportion of post-operative pneumonias was due to infection of the patient by the anesthetist who was suffering from a severe head cold.

Strychnine As a Tonic.—Dr. W. F. MILROY of Omaha, Neb., said that one of the most gratifying therapeutic results he personally had ever witnessed had been in the use of strychnine in pneumonia. There was no more reliable sign of approaching trouble in this disease than the appearance of edema in the dependent portion of the sound lung. He had observed this edema disappear promptly after the injection of 1/40 grain strychnine and, recurring after a few hours, again vanish with the injection of the drug. He had observed this happen repeatedly in the same case and believed he had seen patients by this means carried over a crisis to recovery. The mode of action of strychnine he must mention as concisely as possible. It acted primarily upon the nervous system, including the sympathetic system, probably most strongly upon the medulla and spinal cord. Without discussing the precise mode of action, whatever this might be, it resulted in a stimulation of the physiological activity of practically the whole body. Admitting that cardiac muscular power and blood pressure were not influenced by strychnine, the fact nevertheless remained that the heart action was influenced favorably in certain conditions. For instance, he knew a doctor with a crippled heart which became irregular and intermittent, with distressing subjective symptoms, whenever he overtaxed it a little. Invariably a few doses of strychnine, in this condition, restored the action to normal with disappearance of the unpleasant symptoms. Now, cellular nutrition was not a process of passive absorption. It was an active, vital process which was under the direct control of the nervous system. Therefore, the profound stimulation of the nervous system by full doses of strychnine, directly promoted a new and vigorous cell activity of the whole body, thus tending to restore the opsonic index. The nervous disorders to which he had referred as capable of being successfully treated by strychnine, represented conditions of depression. The nervous system still retained the ability to respond to powerful stimulation which the big doses of strychnine supplied. In reference to administration he would add that though the drug might not be wholly eliminated from the body for as long as eight days, it was mostly gone at the end of twelve hours and therefore the doses must not be too infrequent. Also it was worth while to mention that there was no tendency to habit formation and the largest doses might be abruptly broken off with impunity. Further he would state that this method of treatment was not dangerous. A perfectly safe margin existed between the first appearance of muscular spasm and a really poisonous dose. He had by no means attempted to enumerate the many conditions in which ascending doses of strychnine were indicated. He was convinced that it should be given in much larger doses than was customary and this he was hoping to encourage.

Chronic Appendicitis and Chronic Intestinal Toxemia; Their Association and Differentiation.—Dr. G. REESE SATTERLEE of New York said that a careful study of all cases diagnosed as chronic appendicitis was necessary as was also the use of the *x*-ray in every case. The symptoms of chronic appendicitis and cecal disease was often very similar. Cooperation between surgeon and internist was necessary in the study and treatment of these cases, before and after operation. The proper treatment for chronic intestinal toxemia might clear up symptoms resembling chronic appendicitis. Autogenous colon vaccines should be tried in every case. The internist should be always on the guard for appendicitis in every case of chronic intestinal toxemia, and the surgeon for chronic intestinal toxemia in the case of appendicitis. Medical students should have instructions along these lines and not be taught to diagnose intestinal conditions on symptoms alone.

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-first Annual Meeting, Held at Washington, D. C., May 9, 10, and 11, 1916.

THE PRESIDENT, DR. J. WESLEY BOVEE, WASHINGTON, D. C., IN THE CHAIR.

AN address of welcome was delivered by Dr. Harvey W. Wiley of Washington, D. C., which was responded to by Dr. Edward P. Davis of Philadelphia.

Syphilis in Its Relation to Obstetrics.—Dr. EDWARD P. DAVIS of Philadelphia said that modern knowledge on this subject dated from the discovery of the *Spirocheta pallida* in 1905-6 as the cause of syphilis. The discovery of the Wassermann reaction as a means of diagnosis and that of salvarsan in treatment were important factors. Syphilis could be positively diagnosticated in a newborn infant by finding the characteristic germs in blood taken from the umbilical vein and from the tissues about the umbilicus and umbilical cord. Examination of the bodies of infants dying soon after birth from syphilis showed this germ abundantly present in the important organs of the fetal body. A woman apparently healthy giving birth to a syphilitic infant was herself syphilitic, although she might show for some years no clinical signs or symptoms. In these cases syphilis was conveyed from the ovum to the mother through the medium of the placenta. The mother was said to have latent syphilis and could nurse her child without disturbance in her own health, and with positive benefit to the child. She might, however, at any time develop symptoms of secondary or tertiary syphilis. The Wassermann reaction was unreliable as a positive test for syphilis in parturient women. It might give a positive reaction in cases of severe toxemia and eclampsia where syphilis was absent, and in some other conditions where the mother's general health was seriously disturbed. In the lack of a more reliable means of diagnosis, the Wassermann test should invariably be made in selecting wet nurses, and in all suspicious cases. Syphilis in the acute stage attacking a pregnant woman could often by the use of salvarsan be promptly checked. While the germs causing syphilis would be destroyed, the toxins which they produced would usually cause death of the fetus. If syphilis occurred early in pregnancy, the best result for mother and child would be obtained by mercurial treatment accompanied by the use of iodide of potassium. Where skin lesions were present, hypodermatic or intravenous injections of mercurial solutions were useful. In treating active syphilis in the newborn, salvarsan had been given in the cubital vein with good results. Where salvarsan was used with mother and child, the urine of the patient should be repeatedly examined to determine the presence or absence of arsenic, and the presence or absence of signs of irritation of the kidneys. Should traces of arsenic disappear from the urine, arsenical poisoning might be feared. Syphilis in parturient women greatly increased the mortality and

morbidity for the mother through mixed infection and lesions of the genital organs. Unless promptly detected and treated, it was one of the most important causes of fetal death. No syphilitic man or woman should be allowed to marry unless such had been under observation for six years after the last appearance of symptoms of syphilis.

Syphilis in Relation to Some Social Problems.—Dr. SIGMUND POLLITZER of New York City under the above title dealt with three distinct subjects: (1) Hereditary Syphilis in the Light of To-day. The fact that syphilis could be transmitted from the syphilitic mother to her unborn child was recognized four hundred years ago; but the fact that syphilitic children were born of apparently healthy mothers led to the conclusion that syphilis might be transmitted to the offspring by way of the semen of the father without infecting the mother. In fact, paternal syphilis was regarded as the most frequent form in syphilitic heredity. More extended and definite clinical observation, the discovery of the spirochete on the maternal aspect of the placenta, and the results of the Wassermann test had completely changed our views in this respect. Transmission of spirochete to the ovum might be regarded virtually as a physical impossibility; a spirochete was three times as long as the diameter of a spermatozoid head, and, furthermore, an infected ovum would not develop into a fetus. Colles' law and Profeta's law were true only in the sense that the mother of a syphilitic child and the child of a syphilitic mother already had syphilis, and therefore apparently could not acquire it. The apparently healthy mothers of syphilitic children invariably had a positive Wassermann reaction and generally presented symptoms of syphilis if we followed them long enough. The failure to show a history of the infection in these cases was not very remarkable in view of the statistics of syphilis in women; in only about one-third of the cases that were seen with definite tertiary lesions could a history of infection be elicited. The author emphasized the importance of making a Wassermann test in every case of unexplained abortion instead of resting content with the inadequate explanation of deflections, adhesions, etc. (2) When May the Syphilitic Marry? Recent progress, Dr. Pollitzer said, had greatly changed our view on the gravity of syphilis, especially with reference to lesions of the heart and central nervous system, and at the same time had greatly improved prognostic and therapeutic possibilities. The question of the medical sanction to marriage of the syphilitic had been most earnestly considered forty years ago by Fournier and the principles laid down by him generally followed. The syphilitic might marry when there was a reasonable certainty of his cure. No criterion of cure being possible, formerly a definite period of time and treatment were arbitrarily fixed upon, based on clinical experience. The syphilitic might marry if he had received three years of treatment and had remained free from symptoms for another year or two. Millions of happy marriages proved the wisdom of the rule, but the thousands that resulted in infection of their wives and the birth of syphilitic children proved its inadequacy. The Wassermann test afforded a reliable criterion of cure. The syphilitic woman might marry without risk of infecting her husband after she had reached the tertiary stage of the disease, but she could not bear children without the risk of bearing syphilitic children until she was permanently Wasserman negative. (3) The Control of Syphilis. The attempt to control the incidence of syphilis by segregation, he said, had proved of slight value and, moreover, in Anglo-Saxon countries met with too much prejudice to permit of its enforcement. The control of syphilis must come through education of the public in the risks and dangers of illicit intercourse and education of the physician in the importance of early diagnosis and proper treatment. Various educational bodies were undertaking a campaign of instruction in these matters; even the public press which a few years ago had never printed the word "syphilis" to-day contained educational articles which dealt with the subject frankly. The public was being educated. How far knowledge of the risks and dangers of illicit intercourse would serve as a deterrent was a mooted question. The speaker referred to the excellent results obtained by the prophylactic use of calomel ointment in the armies and navies of the world, a procedure which, if generally employed, would as effectively control the great pox as the smallpox had been controlled by vaccination. The author contrasted the generous provision made for the care of the syphilitic in the hospitals of European cities with the attitude of our American hospitals in most of which the patient with an active syphilis was refused admission. He concluded with a plea to his hearers to exert their personal influence to the end that better hospital facilities be provided for the syphilitic.

Syphilis of the Internal Genital Organs in the Female.—Drs. GEORGE GELLHORN and HUGO EHRENFEST of St. Louis, Mo., contributed a joint paper on this subject, saying that syphilis had always been assumed to be considerably commoner among men than among women; but from certain investigations this supposition could not yet be accepted as conclusive. At any rate, syphilis was common enough in women to constitute a gynecological problem in the widest sense. Not every disease in a syphilitic woman was syphilitic in nature, but syphilis, if present, would exert an influence of its own upon coexistent diseases. Latent syphilis prevailed more in women than in men. The course of syphilis in men differed in many points from that in women. To instance but one of the differences, the relative frequency of tabes and paresis in the two sexes was well known. Primary chancres of the vagina were rare, probably because of certain histological and biological characteristics of the vagina. Tertiary luetic manifestations of the vagina were also extremely rare. They represented, as a rule, the continuation of secondary lesions in the vulva, uterus, or adjoining organs. The isolated submucous gumma broke down early and appeared in the form of a more or less characteristic ulcer. The more destructive processes which eventually led to the formation of fistulæ and strictures, almost always originated in strictures surrounding the vagina. Tertiary lesions of the vagina did not exhibit characteristic symptoms, such as pain or discharge. The primary chancre of the cervix represented the best known and most common type of syphilitic affections of the female internal genitalia. Its frequency had probably been overestimated. Statistics based on a large number of observations had never shown a frequency over 1.5 per cent. of all primary chancres found on the genitalia. Eight personal observations were added by the authors to the few cases found in literature of secondary lesions of the cervix. Syphilis manifested itself upon the cervix in the form of macules, papules, and ulcerations. These forms probably represented three successive stages in the development of a lesion caused by scattered accumulations of the *Spirocheta pallida* in the squamous mucosa of the cervix. The parasite could readily be recovered from the secretion of any of the three forms, and this explained the great infectiousness of secondary lesions. Wassermann reaction was positive in this stage. Syphilis of the pelvic cellular tissue appeared in the form of a diffuse gummatous infiltration which secondarily involved the pelvic peritoneum. To the few cases on record the authors added a personal observation. In almost all instances a diagnosis of malignancy had been wrongly made. In their own case the positive outcome of the Wassermann reaction together with other unmistakable signs of tertiary syphilis about the outer genitals aided in arriving at the correct diagnosis. Specific treatment produced amazingly quick improvement of an apparently hopeless condition. Familiarity with syphilitic lesions in the genital tract must needs prove of eminent practical value to the gynecologist in view of the frequent confusion in the diagnosis of cancer and syphilitic ulcerations or gummata. That occasionally a patient is subjected to a serious radical operation who could have been cured by antiluetic treatment there could be no doubt.

The Specificity of the Wassermann Reaction.—Dr. RUDOLPH BUHMAN of St. Louis, Mo., gave the results of the Wassermann reaction in a series of diseases from individuals supposed to be free from syphilis, with especial reference to malignant diseases. Of 132 cases of malignant diseases, including carcinoma, sarcoma, and malignant adenoma, nine gave a positive reaction; six of these nine cases suffered from both malignancy and syphilis; the other three cases were not under observation long enough.

Occurrence of Syphilis in the University of Michigan Obstetrical and Gynecological Clinic.—Dr. REUBEN PETERSON of Ann Arbor, Mich., presented the following summary and conclusions: (1) Only by routine Wassermann tests would the obstetrician and gynecologist best serve the interests of his patients. (2) Especially was this true in hospital practice where even careful histories failed to arouse suspicion of latent

syphilis. (3) Out of 2,000 in-patients in the University Hospital, excluding two services, the proportion of syphilitics was 6 per cent. (4) The nature of the hospital material would determine the percentage of lues, but in the average hospital the ratio would not be far from 8 to 10 per cent. if the entire hospital population be included. (5) The same held true for the proportion of syphilis in any special clinic, the percentage varying according to the nature of the material. (6) The percentage of lues in 381 cases in the University Maternity was 4.7 as shown by the Wassermann reactions and expert physical examinations. (7) In 18 cases of syphilis among the number examined, only eight or less than half gave a history of lues. (8) In only the same number (eight) were there positive physical signs of lues. (9) As shown by the histories of the 18 cases, there was a greater chance for the syphilitic mother treated by salvarsan and mercury to give birth to a living full-term child than where no treatment be given during pregnancy. (10) The newborn infants of the mothers so treated did not give positive Wassermann reactions, although undoubtedly they were syphilitic and later would probably show signs of the disease. (11) A certain proportion of the newborn children of untreated syphilitic mothers would give positive Wassermanns. (12) Out of 390 gynecological patients subjected to the Wassermann test, 22 or 5.6 per cent. gave positive reactions. (13) In only five of the 22 luetic patients was there a history of syphilis. (14) Hence the importance of such examinations, or a serious general disease would be overlooked and the gynecological patient would remain uncured.

Relationship of Syphilis to Miscarriage and Fetal Abnormalities.—Dr. Fred L. Adair of Minneapolis presented data from a series of cases showing the relative frequency of miscarriage in cases giving evidence of syphilis and those showing no signs of lues. The frequency of luetic manifestations in mothers who gave birth to monstrosities and malformed children was considered, after which he presented some observations on the relationship of syphilis to habitual abortion.

How Closely Do the Wassermann Reaction and the Placental Histology Agree in the Diagnosis of Syphilis?—Dr. J. Morris Slemons of New Haven, Conn., stated that in 360 consecutive confinements the Wassermann test had been made on the mother's blood and the placenta had been studied for evidences of syphilis. The most notable disagreement occurred in cases of toxemia of pregnancy which not infrequently presented a faintly positive Wassermann reaction, though the placenta was normal. Except for this fact, the results of the Wassermann test and of the placental examination stood in very close agreement.

Experimental Syphilis.—Dr. F. W. Baeslack of Detroit stated that the causal relationship of the treponema pallidum to lues was established (*a*) by the observation of the occurrence of the organisms in the syphilitic lesions incident to the various stages of the disease; also, the distribution of the pallida in the lesions of acquired and congenital syphilis. (*b*) The successful inoculation of lower animals from human lesions, thereby producing syphilis experimentally in rabbits, monkeys, and other animals; the methods employed and discussion of the character of the lesions, and the observation of generalized syphilis in experimentally inoculated animals. (*c*) The growing of the treponema pallidum in culture media free from contamination, the transfer of these cultures through many generations, and the successful inoculation of lower animals with the cultivated organisms; the loss of virulence of the organisms against the lower animals after extended cultivation; and the cultural characteristics and morphology of the pallida. (*d*) Immunological studies, pseudoprimary lesions, and true reinfection, as well as superinfection, as expressed in the lesions in the various stages of syphilis, which do not harmonize with our conception of immunity. The author spoke of attempts at immunization by means of pallida vaccines, and described the occurrence of agglutinins in the serum of animals treated with suspensions of dead pallida. He spoke of the absence of immunity as demonstrated by the ability to reinoculate animals which had recovered spontaneously or subsequent to treatment. He pointed out that an altered reactivity of the body was the possible explanation for the occurrence of the lesions peculiar to the various stages of syphilis.

Syphilitic Fever.—Dr. Frederick J. Taussig of St. Louis, Mo., read a paper on this subject, in which he presented the following summary: "(1) The diagnosis of syphilitic fever can rarely be made with absolute certainty, but we should more often consider it as a possibility and institute antiluetic measures in suitable cases. (2) Secondary syphilitic fever occurs in a mild form in 20 per cent. of patients at the outbreak of the rash and at times is prolonged and more severe in its course. (3) Late secondary syphilitic fever is occasionally seen in a pronounced form after confinement or in gynecological patients. (4) Tertiary syphilitic fever is practically never due to syphilitic lesions in the female genital tract. One such case is reported by the author. It may, however, complicate a gynecological or obstetrical condition, and, owing to the difficulty in locating the site of the tertiary lesion, lead to a wrong diagnosis as to the cause of the fever. All doubtful cases should be subjected to a Wassermann test and, if positive, given antiluetic treatment. (5) Syphilitic fever is probably due to the reaction of the body to the toxins produced by the spirochete which, under certain circumstances, or in certain individuals, gain an entrance into the circulation.

Syphilis of the Body of the Uterus.—Dr. Charles C. Norris of Philadelphia stated that it was only since the discovery of the *Spirocheta pallida* and the development of the Wassermann test that the true frequency of syphilis had been recognized. Probably 1 to 4 per cent. of women were syphilitic. The disease was rare in the body of the uterus. Theoretically chancres might occur in the body of the uterus as the result of spermatozoic infection and this avenue of ingress might account for some of the cases of syphilis which developed without demonstrable primary sore. No chancre had, however, ever been demonstrated in this location. Some authors believed mucous patches might occur in the endometrium. This, however, was unproven. There were two varieties of syphilitic endometritis: (*a*) gummatous, and (*b*) a less characteristic form in which the blood vessels were especially affected. Syphilis of the myometrium occurred as (*a*) gumma and (*b*) a diffuse metritis, the most characteristic lesions of which were in the blood vessels. Many cases were reported as syphilis on insufficient grounds. Hemorrhage in the form of menorrhagia was a frequent symptom. Leucorrhea and pain occurred. The author reported the following case: Patient aged 36 years; married 12 years; III-para; last child seven years ago. Six years ago she contracted syphilis, and since then had had three miscarriages, two, three, and five months respectively, the last six months ago; mixed treatment until nine months ago. Menorrhagia developed five months ago; hemorrhages profuse and produced severe anemia with its accompanying symptoms. When brought to the hospital she had been bleeding for 12 days. Physical, abdominal, and pelvic examinations negative; hemoglobin 52; red blood count 5,000,000; white blood count 4,500; Wassermann strongly positive; diagnostic curettage during which fundus was perforated. Because of age of patient, three living children, history of intractable bleeding, and perforation of uterus, supravaginal hysterectomy was performed; convalescence normal; salvarsan administered; pathological examination of specimen showed uterus normal in size and shape, but so friable that its walls could be squeezed through at any point with thumb and forefinger. Histological examination showed the endometrium slightly thickened and infiltrated, with chronic inflammatory products. Angiosclerosis of vessels; myometrium more or less inflamed; much edema; marked angiosclerosis of vessels and complete obliteration of some; inner coats of vessels chiefly affected; lymphatic spaces dilated. In many fields muscle fibers partially separated from one another. The diagnosis of syphilis in this case was not positive, as the *Spirocheta pallida* was not demonstrated or searched for. Etiology was suspected, and the Wassermann report was not secured until some days following operation, by which time specimen had been fixed in formalin solution, thereby making the demonstration of the *Spirocheta pallida* very difficult. The diagnosis was based upon the following: that the patient contracted syphilis six years ago, and since then had had three miscarriages; that the symptoms referable to the uterus developed three months after cessation of antisyphilitic treatment, and one month after the last miscarriage; that these were the symptoms usually produced by syphilis of the uterine body; that the histological findings, especially blood vessel changes, were those of syphilis. The hemorrhage and

discharge were not the result of pyogenic infection following a miscarriage as they did not occur with either of the two former miscarriages, but developed one month after the last. These facts led the author to ascribe the uterine lesions to syphilis. Three similar cases were recorded in the literature.

Incontinence of Urine in Women.—Drs. Howard C. Taylor and Charles H. Watt of New York City contributed a joint paper on this subject, in which the following conclusions were drawn: (1) While incontinence of urine is due to a lesion of the sphincter vesicæ only, it is relatively an infrequent symptom. (2) Incontinence of urine due to a lesion of the sphincter vesicæ associated with other lesions is a frequent and important condition. (3) In pelvic operations for lesions associated with incontinence of urine as a symptom, care should be used to remove all drag or downward traction on the anterior vaginal wall and frequently to infold the sphincter vesicæ.

(*To be continued.*)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

State Board of Medical Examiners of Maryland.

June 20, 1916.

ANATOMY.

1. Describe articulations of superior maxillary bone.
2. Describe the elbow joint, name the ligaments, and give their attachments.
3. Give location and size of stomach when empty.
4. Superficial and deep origin and arrangement of fibers in commissure, of optic nerves.
5. Where would you locate lesion in a case of aphasia?
6. Describe valves of heart.
7. Give origin, insertion, action and nerve supply of following muscles: (*a*) Obliquus internus. (*b*) Obturator externus. (*c*) Omohyoideus. (*d*) Serratus magnus.
8. Through what vessels would circulation be established after ligation of brachial artery in lower third?
9. Where are semicircular canals located, and by what bony openings do they communicate with the middle ear and with the cranial cavity?
10. What is the mesentery?

PHYSIOLOGY.

1. (*a*) Describe the normal flow of blood through the arteries, capillaries and veins, and factors which cause the flow of each. (*b*) Give the relative rates of circulation in the arteries, capillaries and veins, and state how long it takes the blood to make a complete circuit of the body. (*c*) What is the total quantity of blood as compared with weight of the body?
2. (*a*) Define absorption and secretion. (*b*) Give some of the theories of absorption. (*c*) State difference between internal and external secretions, and give examples.
3. (*a*) Define animal heat and give sources. (*b*) State some of the conditions which produce variations in the normal temperature. (*c*) Give normal temperature in axilla, mouth, and rectum.
4. What is accomplished physiologically by the portal circulation?
5. Where is the respiratory center located and what is internal respiration?
6. (*a*) What are the functions of the bile—the ingredients and how secreted? (*b*) Give tests for bile salts and bile acids.
7. Describe the function of the Eustachian tube, retina, iris, cornea, and tympanic membrane.
8. Give the locations at which the various heart sounds can be best heard and state the cause of each sound.
9. Discuss briefly the physiology of the nervous system and give a classification of the nerve cells.
10. What is blood pressure—mode of ascertaining—the average blood pressure in male and female.

CHEMISTRY.

1. Give symbol, valence and one important compound of each of ten elements.
2. Describe nitrogen. In what form is it chiefly eliminated from the body? Name several compounds containing nitrogen and give formulæ.
3. Describe lead. (*a*) Which of its compounds is used in medicine? (*b*) From what sources may chronic lead poisoning come?
4. Give two antidotes for phosphorus and explain their action.
5. Give a chemical antidote for each of the following and explain mode of action: Phenol, nitric acid, oxalic acid, mercuric chloride.
6. Wood alcohol and grain alcohol: (*a*) Give formulæ and state the class of chemical substances to which they belong. (*b*) How would you treat a case of poisoning by the former, supposing the case were seen shortly after ingestion of the substance?
7. Why is a salt of mercury incompatible with KI?
8. What is synthesis? Name three synthetic organic substances used in medicine.
9. Describe method of determining the sugar content of the blood.
10. What substance is used as an antidote for most alkaloids and how does it act?

MATERIA MEDICA.

1. Mercury; the official preparation, doses, and incompatibles.
2. Lead; the official preparations and incompatibles.
3. Write a prescription using official terms, containing at least three ingredients, for diarrhea in an adult. Also one for a child 2 years old containing three ingredients.
4. Give the average hypodermic dose for an adult of apomorphine, morphia sulphate, nitroglycerin, atropine sulphate, and pituitary extract.
5. Ergot; the official preparations and doses.
6. Potassium: the official preparations and doses.
7. Name three drugs which are motor nerve depressants; three which are sensory nerve depressants, and give adult dose of each.
8. (*a*) Define antiseptics and name three that are used internally with adult dose. (*b*) Name three that are used externally and give strength of same, using official terms.
9. Write a prescription as a diuretic containing three ingredients, using official terms.
10. Define antitoxins and vaccines. Name those in most general use, give source and method of administering.

THERAPEUTICS.

1. Flexile collodion, and cantharidal collodion; their therapeutic uses.
2. Give the therapy of boric acid and methods of use.
3. Acid salicylicum, its therapy and usual combination for internal administration.
4. Sodii bicarbonas, properties and uses, incompatibles.
5. Spiritus ætheris nitrosi, its properties, uses and adult dose.
6. Aethylis chloridum, properties and uses, and objections to its use.
7. Alumen, properties and uses, value of the exsiccated.
8. Arseni trioxidum, therapy, liquid preparations and state which can be administered with acids.
9. Hexamethylenamin, properties and uses, mode of action and danger from large doses.
10. Write a prescription in Latin, without abbreviation, containing four ingredients (with "Fowler's solution" as one) stating condition for which used.

ANSWERS.

ANATOMY.

1. The *superior maxillary bone articulates with*: The frontal, ethmoid, malar, nasal, lacrimal, palate, vomer, inferior turbinated, and the superior maxillary of the opposite side; sometimes it articulates also with the sphenoid.
2. The *elbow-joint* "is a ginglymoid articulation formed above by the lower extremity of humerus, below by upper extremities of ulna and radius. Its ligaments are external and internal lateral, anterior and posterior ligaments. *External lateral* arises from external condyle of humerus and is inserted into outer margin of ulna. *Internal lateral*, much stronger, consists of two portions; *anterior* arises from fore part of internal condyle to be inserted into coronoid process, and *posterior* from back part of condyle to inner margin of olecranon.

Anterior ligament arises above coronoid fossa, and is inserted into coronoid process of ulna and orbicular ligament. *Posterior ligament*, attached above olecranon fossa, and below to olecranon process of ulna. The anterior and posterior ligaments become continuous with the lateral to encircle the joint."—(*Young's Anatomy.*)

3. The *stomach*, when empty, lies in the epigastric and left hypochondriac regions, at the back part of the abdomen, and is immediately below the diaphragm; its length is about 10 inches, its breadth 3 to 4 inches, and its antero-posterior diameter about 2 to 3 inches.

4. The *optic nerves* arise from the forepart of the optic commissure, which is the decussation of the fibers in the optic tract; most of the fibers decussate (these are arranged internally), a few pass to the eye of the same side, and a few of the posterior fibers do not decussate but pass across the commissure from one cerebral hemisphere to the other.

5. In *aphasia* (in a right-handed person) the lesion would be located in the posterior part of the third frontal convolution of the left cerebral hemisphere.

6. *The valves of the heart* are: In the *right auricle*, the Eustachian and coronary valves; the former is situated between the anterior margin of the inferior vena cava and the auriculoventricular orifice. In the fetus it directs the blood from the inferior vena cava through the foraman ovale into the left auricle; the coronary valve prevents the regurgitation of the blood into the coronary sinus during the auricular contraction. In the *right ventricle* are the tricuspid and semilunar valves; the former prevents the blood in the right ventricle from flowing back into the right auricle during ventricular cystole; the latter guards the orifice of the pulmonary artery. In the *left ventricle* are the mitral and semilunar valves; the former acts similarly to the tricuspid; the latter guards the orifice of the aorta. The *tricuspid valve* consists of three cusps, or segments, the bases of which are attached to a ring around the auriculo-ventricular opening, while the edges are free in the ventricle and are attached to the upper end of the chordæ tendineæ. The *pulmonary semilunar valve* is composed of three segments, attached at their bases to the wall of the pulmonary artery and having on their free edges a nodular projection, the *corpus Arantii*. The *initial valve* has two cusps, and is otherwise of similar structure to the tricuspid valve. The *aortic semilunar valve* resembles the pulmonary valve in structure.

7. OBLIQUUS INTERNUS. *Origin*: Outer half of Poupart's ligament, anterior two-thirds of crest of ilium, and from lumbar fascia. *Insertion*: Crest of pubis, pectineal line, linea alba, and cartilages of seventh, eighth, and ninth ribs. *Action*: Compression of abdominal viscera (thus aiding in vomiting, urination, defecation, and parturition), compression of thorax (thus aiding in expiration). *Nerve supply*: Lower intercostal nerves, and iliohypogastric.

OBTURATOR EXTERNUS. *Origin*: Body and ramus of os pubis, ramus of ischium, and obturator membrane. *Insertion*: Digital fossa of femur. *Action*: External rotator of thigh. *Nerve supply*: Obturator nerve.

OMOHYOIDEUS. *Origin*: Upper border of scapula. *Insertion*: Body of hyoid bone. *Action*: Depresses and retracts hyoid and larynx. *Nerve supply*: Descendens and communicans hypoglossi.

SERRATUS MAGNUS. *Origin*: Eight upper ribs. *Insertion*: Inner margin of dorsal border of scapula. *Action*: Elevates ribs in inspiration, is used in pushing, and raising the arm. *Nerve supply*: Posterior thoracic nerve.

8. When the *brachial artery is ligated in the lower third*, the *collateral circulation* is carried on as follows: The superior profunda anastomoses with the radial recurrent, and posterior interosseus recurrent; and the inferior profunda anastomoses with the posterior ulnar recurrent and anastomotica magna.

9. The *semicircular canals* are located in the internal ear, above and behind the vestibule. They open into the vestibule by five apertures: The ampulla ossea superior, crus commune, ampulla ossea posterior, macula cribrosa inferior, and ampulla ossea lateralis.

10. The *mesentery* is the fold of peritoneum which connects the jejunum and ileum with the posterior abdominal wall.

PHYSIOLOGY.

1. The *circulation of the blood* is the course or circuit of the blood from the heart, through the body and back to the heart. Beginning at the left ventricle of the heart, the blood flows through the left semilunar valve into the aorta, from which branches are distributed to every part of the body, through the capillaries to the veins, from the veins to the venæ cavæ, thence to the right auricle of the heart. From the right auricle, through the tricuspid valve to the right ventricle, thence through the right semilunar valve to the pulmonary artery to the lungs, from the capillaries in the lungs to the pulmonary veins, thence to the left auricle, and through the mitral valve to the left ventricle, to begin the circuit again.

The circulation of the blood is regulated in (a) *the arteries* by: (1) The elasticity and tone of the arteries, (2) the force and frequency of the cardiac contractions, (3) the resistance in the capillaries; (b) in the *capillaries* it is regulated by (1) the action of the heart, (2) the action of the arteries; (c) in the *veins* it is regulated by (1) the action of the heart, (2) aspiration of the thorax, (3) the contraction of the muscles, and (4) slightly by the valves in the veins.

The velocity of the blood current is about 1 foot per second in the arteries; about 1 inch per minute in the capillaries; and about 8 inches a second in the veins. The complete circulation around the body is said to occupy a little less than half a minute.

The total quantity of blood was formerly said to be about one-thirteenth of the weight of the body; recently this figure has been altered to one-twentieth of the body weight.

2. *Absorption* is the process by which the products of digestion are taken up into the general circulation. It occurs with greatest activity in the villi of the small intestine.

The products of digestion find their way into the blood by two routes: (1) By the blood-vessels of the gastrointestinal tract, which unite to form the portal vein; and (2) by the lymph vessels of the small intestine, which converge to empty into the thoracic duct. The water, inorganic salts, proteids and sugar go by way of the portal vein to the ascending vena cava; and the fats go by way of the thoracic duct to the junction of the left subclavian and internal jugular veins.

The process by which absorption is accomplished is partly physical (osmosis and filtration), and is also due in part to selective action. To be absorbed by the blood-vessels or lacteals the substances must be in a fluid state, and the more dilute the solution the more rapid the absorption. The absorbed matter must be rapidly removed and fresh blood supplied to the capillaries.

Secretion means the process by which some of the constituents of the blood are separated from the blood stream (by the activities of the capillary endothelium, as the blood passes through the capillaries) and elaborated into other material. The products of secretion vary with the gland or membrane where it occurs. Thus: Saliva, tears, milk, bile, gastric juice, synovial fluid, serous fluid, pancreatic juice.

Internal secretions: It is generally held now that the glandular organs, chiefly the pancreas, liver, and the ductless glands, produce a secretion, peculiar in each case to the particular gland producing it, and which is supposed to be given off to the blood or lymph, and to have some peculiar value in the general metabolism of the body. Such secretions are called internal secretions, in contradistinction to the previously known secretions, which are carried off by a duct, and are known as external secretions.

3. *Animal heat* is the heat produced in living organisms by the processes of oxidation.

Heat is produced in the body by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord.

Conditions which produce variations in the normal temperature: Age, time of day, position, whether sleeping or awake, whether working or resting. The normal temperature, in *axilla*, is about 37° C.; in *mouth*, about 37.5° C.; in *rectum*, about 38° C.

4. The function of the portal circulation is to carry the venous blood from the stomach, intestines, pancreas and spleen to the liver. The blood thus carried is loaded with the products of absorption. In the liver this blood enters into close relation with the hepatic cells, and is finally carried to the inferior vena cava. Further, the ordinary functions of the liver are due, in part, to the portal circulation. These functions are: Manufacture and storage of glycogen; formation of urea, uric acid and creatinin; formation of bile, and manufacture of heat.

5. The *respiratory center* is situated in the lowest part of the floor of the fourth ventricle, at the calamus scriptorius. *Internal respiration* is the interchange of gases between the blood or lymph and the cells of the various tissues of the body. The term is used in opposition to *external respiration*, which is the interchange of gases occurring in the lungs.

6. The *functions of the bile* are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach, and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

Bile is composed of water, sodium glycocholate, sodium taurocholate, mucin, cholesterin, lecithin, fats, pigments (bilirubin and bilverdin) and inorganic salts (chiefly sodium chloride, potassium chloride, calcium phosphate, magnesium phosphate, and iron phosphate).

"The *secretion of bile* is a continuous process, and in periods when digestion is not taking place, bile accumulates in the gall-bladder. About the third hour after a meal is taken the gall-bladder is emptied into the lumen of the duodenum, but the mechanism by which the contents are expelled has not yet been ascertained. Bile continues to flow into the intestine during the digestive process, and, later, again accumulates in the gall-bladder. . . . So far as is known, the secretion of bile is independent of nervous action, and is excited (1) by the reabsorbed bile salts, and (2) by secretin."—(Bainbridge and Menzies' *Essentials of Physiology.*)

Test for bile-salts: Sprinkle some flowers of sulphur on the surface of a solution containing bile salts; the sulphur will sink, whereas on most other liquids it will float.

Test for bile-acids: To a thin film of bile in a capsule add a drop of solution of cane sugar and a drop of concentrated sulphuric acid; a purple color is obtained.

7. *Function of the Eustachian tube* is: (1) To maintain equilibrium between the atmospheric pressure in the middle ear and the outside air. (2) The cilia on the epithelium lining the tube filter the incoming air from the pharynx and so aid in keeping bacteria out of the middle ear. (3) It may act as a drainage tube for the middle ear. (4) It may possibly have some function as a resonating tube, as may be observed when it is closed in catarrhal conditions, when the voice sounds strange both to the patient and to others.

Function of the retina is to receive the stimulus of light and transform it into a nervous impulse which is carried to the brain by the optic nerve.

Function of cornea is to allow light to pass from outside to the retina.

Function of iris is to regulate the amount of light which enters the eyeball and falls upon the retina; it also regulates the size of the pupil, and reduces both spherical and chromatic aberration.

The *function of the typmanic membrane* is to receive the vibrations of the atmosphere which are transmitted to it.

8. There are two normal heart sounds which follow in quick succession, and are succeeded by a pause. The first, or systolic, sound is dull and somewhat prolonged, the second, or diastolic, sound is sharper and shorter. The sounds may be expressed by the syllables *lubb—dup.*

The first sound is heard best at the apex beat in the fifth left intercostal space; the second sound is heard best over the second right costal cartilage.

The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

9. *Physiology of the Nervous System:* "The primary elements of the nervous system are the neurones and the neuroglia, the former being the discharging and conducting structures, and the latter the supporting. The *neurone* is the essential element of the nervous system, which may be regarded as built up of an enormous number of them arranged in series, and occupying definite tracts. A neurone consists of a nerve cell and its branches (axon and dendrons or dendrites). The *dendrons* belonging to a single cell may be many, or there may be but one; in either case they are short processes, soon subdivided into many terminal branches forming an arborisation. They are made up of fibrillæ, and of granular matter lying between the fibrillæ, which are continuous, through the body of the cell itself, with the fibrillæ of other dendrons or of the *axon.* This process, entirely composed of fibrillæ, gives off collaterals at right angles to its course, and these, like the axon itself, often end in an arborisation around the dendrons of another nerve cell. These places of linkage of one neurone with another are called synapses. An axon may be either long or short; in the former case it does not branch for a considerable distance, becomes surrounded with myelin, and passes as a nerve fiber into the white matter; in the latter it breaks up into branches close to its cell, which is known as a "link cell," and is confined to the gray matter alone. The dendrons conduct impulses *toward* the cell, the axons *away* from it.

"The *nerve* cell itself, besides its nucleus and nucleolus and the fibrillæ which traverse it, contains a series of angular granules (Nissl's bodies) similar to those of the dendron. They stain deeply with methylene blue, and are an index of the state of health, or degeneration of the cell. The multiplication of nerve cells ceases shortly after birth, but their growth is active, and they have great reparative power.

"The *neuroglia* is composed of a network of delicate interlacing fibrils containing a number of nucleated cells (Deiter's cells) embedded in it. It everywhere interpenetrates the nervous elements, but is most abundant round the central canal of the cord and the ventricles of the brain, and in the substantia gelatinosa of Rolando, which lies at the tip of the posterior cornu of the cord. In the various "scleroses," it is increased at the expense of the nervous elements.

"A neurone is 'efferent' or 'afferent,' according as its axon carries impulses from the central nervous system toward the periphery, or from the periphery toward the center. By the superposition of one efferent neurone upon another, or of one afferent neurone upon another, efferent, descending, or *motor*, and afferent, ascending, or *sensory* paths are built up, which occupy definite positions in the spinal cord and brain."—(Wheeler and Jack's *Handbook of Medicine.*)

Classification of nerve cells.—Schäfer classifies nerve cells as follows: "1. *Afferent cells*, which receive impressions at the periphery to convert them into impulses. The latter then pass toward the central nervous system. 2. *Efferent cells*, which send out nervous impressions toward the periphery. 3. *Intermediary cells*, which receive impressions from afferent cells to transmit them directly or indirectly to efferent cells. 4. *Distributing cells*, which occur near the periphery and, receiving impulses from efferent cells, distribute them to involuntary muscles and secreting cells. The cells of this class belong to the so-called sympathetic system."

10. *Blood pressure* is the pressure of the blood due to the ventricular systole, the elasticity of the arterial walls, and the resistance of the capillaries. The normal arterial blood pressure varies; the systolic pressure being (in males) about 120 to 150 mm. of mercury, and the diastolic from about 90 to 120 mm. of mercury. In females, the pressure is from 10 to 15 mm. lower. Blood pressure is *maintained* by the contraction of the heart, the peripheral resistance, and the elasticity of the arterial walls.

Blood pressure is estimated by a sphygmomanometer. The individual whose blood pressure is about to be recorded should be placed in such a position that his heart, the artery the blood pressure of which is to be determined, and the manometer are at the same level. It is usual to record the pressure in the brachial artery. The india-rubber bag of the instrument should be wrapped round the bared arm, the metal covering of the bag should then be adjusted, and firmly strapped in position. The india-rubber tube leading from the bag is then adjusted to the proximal limb of the U-shaped manometer which contains mercury. The experimenter places the index finger of his left hand over the radial pulse of the subject, and with his right hand he compresses the syringe and so drives air into the india-rubber tube and the india-rubber bag around the individual's arm. The pressure of the air in the bag around the arm is recorded by movement of the mercury from the proximal to the distal limb of the manometer. The operator keeps on pressing the syringe until oscillatory movements are seen at the surface

of the mercury in the distal limb of the manometer; the mean point of maximum oscillations registers the diastolic pressure. If the pressure in the bag is still further increased, the oscillations diminish in amplitude and finally disappear, and at this point the pulse can no longer be felt at the wrist. The height of the mercury supported then registers the amount of systolic pressure. It will then be noted that the mercury has descended in the proximal limb of the manometer, and has ascended in the distal limb of the manometer: the difference between the two mercurial levels will be the blood pressure of the brachial artery. The normal systolic pressure in man is about 120 mm. Hg, and the diastolic pressure about 100 mm. Hg. In women the pressures are about 10 per cent. less. In children the systolic pressure may be as low as 90 mm. Hg, with a diastolic pressure of about 80 mm. Hg.—(R. Hutchison.)

1. CHEMISTRY.

Element.	Symbol.	Valence.	One Compound.
Hydrogen	H.	1	Hydrogen monoxide, H_2O
Oxygen	O.	2	Nitrogen monoxide, N_2O
Carbon	C.	4	Ether $(C_2H_5)_2O$
Nitrogen	N.	3 or 5	Ammonia, NH_3
Chlorine	Cl.	1	Hydrochloric acid, HCl
Potassium	K.	1	Potassium iodide, KI
Sodium	Na.	1	Sodium chloride, NaCl
Arsenic	As.	3 or 5	Arsenic trioxide, As_2O_3
Calcium	Ca.	2	Calcium sulphate, $CaSO_4$
Iron	Fe.	2 or 4	Ferric chloride Fe_2Cl_6

2. *Nitrogen* is a colorless, odorless, tasteless gas, noncombustible, very sparingly soluble in water, very slow to enter into combination; it is not poisonous, but it does not support respiration.

It is chiefly eliminated from the body in the form of urea.

Compounds containing nitrogen: Urea, CON_2H_4; ammonia, NH_3; nitrogen monoxide, N_2O; nitrogen dioxide, NO; nitrogen monoxide, N_2O_3; nitrogen tetroxide, N_2O_4; nitrogen pentoxide, N_2O_5; nitrous acid, HNO_2; nitric acid, HNO_3; hydrocyanic acid, HCN; lead nitrate, $Pb(NO_3)_2$; ethyl amin, $C_2H_5NH_2$.

3. *Lead* is a bluish-white metal, soft and pliable; not very ductile or malleable, a poor conductor of electricity but somewhat better conductor of heat, is readily oxidized when exposed to air; its atomic weight is 207, and its valence 2.

The compounds used in medicine are the acetate, oxide, iodide and nitrate.

Sources of chronic lead poisoning: Contamination of drinking water which has been in contact with lead; the use of food or chewing tobacco which has been wrapped in tinfoil containing excess of lead; drinking of beer or other beverages which have been in contact with pewter; handling of lead or its alloys; manufacturing processes in which lead or its compounds are used.

4. *Two antidotes for phosphorus*: I. Old, acid, unrectified French oil of turpentine, which forms with the phosphorus an inert compound of phosphorous acid. 2. Copper sulphate, which, besides being an emetic, may coat the phosphorus with copper.

5. *Chemical antidote for phenol*, sodium sulphate, which with phenol forms the insoluble phenolsulphonate.

Chemical antidote for nitric acid is magnesium oxide or hydroxide, which will dilute and neutralize the acid.

Chemical antidote for oxalic acid is syrup of lime, which forms the insoluble calcium oxalate.

Chemical antidote for mercuric chloride is milk, which forms an insoluble albuminate.

6. *Wood alcohol* is methyl alcohol, $H.CH_2OH$; *grain alcohol* is ethyl alcohol, CH_3CH_2OH. They both belong to the class of hydrocarbon hydroxides.

Treatment of poisoning by wood alcohol: Wash out the stomach, and administer a hypodermic of pilocarpine; strychnine is a serviceable tonic, and the iodides are said to benefit the amaurosis. Rectal injections of normal saline solution are useful.

7. Mercurous chloride is incompatible with KI because by the union of these two the soluble mercuric iodide is formed, which is poisonous. Thus $Hg_2Cl_2 + 2KI = 2KCl + Hg_2I_2$.

8. *Synthesis* is the chemical building up of a compound out of simpler compounds or elements.

Three synthetic organic substances used in medicine: Salicylic acid, antipyrine, and urotropin.

9. *To detect sugar in the blood*: A small amount of blood, obtained by wet cupping, is first freed from proteids, by adding an equivalent weight of sodium sulphate, and then boiling, and filtering, the filtrate thus obtained being used for the test. A solution is now made in a test-tube, by mixing two parts of phenyl-hydrazin hydrochloride and four parts of sodium acetate with about six cubic centimeters of water, and gently heating the fluid, if necessary, to effect solution. Five cubic centimeters of the proteid-free filtrate, while still warm, are added to an equal volume of the test solution. This mixture is then placed in a test-tube half filled with water, heated for half an hour in a water-bath, and allowed to stand until cool. When cooling of the mixture has occurred, it shows under the microscope the presence of the characteristic yellowish crystals of phenyl-glucosazon, either detached or in clusters, together with colorless crystals of sodium sulphate. (DaCosta's *Clinical Hematology*).

10. The antidote for most alkaloids is tannin; it precipitates the alkaloids and their salts and forms tannates which are comparatively insoluble.

MATERIA MEDICA.

1. MERCURY. *Preparations and doses*: Emplastrum hydrargyri; Hydrargyrum cum creta, dose 4 grains; Massa hydrargyri, dose, 4 grains. Unguentum hydrargyri; Unguentum hydrargyri dilutum; Hydrargyri oxidum rubrum; Unguentum hydrargyri oxidi rubri; Hydrargyri oxidum flavum; Unguentum hydrargyri oxidi flavi; Oleatum hydrargyri; Hydrargyri chloridum corrosivum, dose 1/20 grain; Hydrargyri chloridum mite, dose (laxative), 2 grains; (alterative) 1 grain; Pilulæ catharticæ compositæ, dose 2 pills; Hydrargyri iodidum rubrum, dose 1/20 grain; Liquor arseni et hydrargyri iodidi, dose 1½ minims; Hydrargyri iodidum flavum, dose, 1/5 grain; Liquor hydrargyri nitratis; Unguentum hydrargyri nitratis; Hydrargyrum ammoniatum; Unguentum hydrargyri ammoniati.

Incompatibles: *Mercuric chloride* is incompatible with alkalies and their carbonates, potassium iodide, tartar emetic, silver nitrate, lead acetate, lime water, and tannic acid; with *mercurous chloride*, mineral acids, alkalies, ammonia, carbonates, chlorides, cocaine, iodides, lead salts, lime water, sodium bicarbonate, and sugar.

2. LEAD. *Official preparations*: Plumbi acetas, plumbi iodidum, plumbi nitras, plumbi oxidum, liquor plumbi subacetatis, liquor plumbi subacetatis dilutus, ceratum plumbi subacetatis, emplastrum plumbi, emplastrum adhæsivum, unguentum diachylon.

Incompatibles: Alkalies, mineral acids and their salts, opium, potassium iodide, vegetable acids, bromides, carbonates, chloral hydrate, glucosides, salicylic acid, sulphates, tinctures.

3. *For diarrhœa, in an adult*:

℞ Salolis, 5j.
Bismuthi subnitratis.
Cretæ preparatæ āā 5iv.
Pulveris acaciæ q.s.
Aquæ cinnamoni q.s. ad ℥vj. M.
Sig.: A dessertspoonful every 2 or 3 hours.

For diarrhœa, in a child 2 years old:

℞ Bismuthi salicylatis, 5ij.
Glycerin, 5ij.
Misturæ cretæ, q.s. ad ℥iij. M.
Sig.: One teaspoonful every 2 or 3 hours, as necessary.

4. *Average hypodermic dose*: Of apomorphine hydrochloride, gr. 1/10 (as an emetic); of morphine sulphate, gr. ⅛; of nitroglycerin, ♏.j; of atropine sulphate, gr. 1/150; of pituitary extract, ♏.x.

5. ERGOT. *Official preparations and doses*: Extractum ergotæ, gr. iv; fluidextractum ergotæ, ♏.xxx; vinum ergotæ, 5ij.

6. The *potassium salts, with doses*, are: The acetate, gr. xxx; bicarbonate, gr. xxx; bitartrate, gr. xxx; bromide, gr. xv; carbonate, gr. xv; chlorate, gr. iv; citrate, gr. xv; effervescent citrate, gr. lx; cyanide, gr. 1/5; dichromate, gr. 1/5; ferrocyanide, gr. vij; hypophosphite, gr. vij; iodide, gr. vij; nitrate, gr. vii; permanganate, gr. j; sulphate, gr. xxx; and potassium and sodium tartrate, 5ij.

7. *Three motor depressants*: Aconite (dose of tincture, 10 minims); digitalis (dose of infusion, 5ij); camphor (dose of monobromated camphor, gr. ij).

Three sensory depressants: Opium, dose gr. j; belladonna (dose of tincture, ♏. viij); chloral hydrate, dose gr. xv.

8. *Three antiseptics used internally*: Phenol, dose gr. j, well diluted; creosotum, dose ♏. iij; hexamethylenamine, dose gr. iv.

Three antiseptics used externally: Phenol, 1 to 5 per

cent. solution; hydrargyri chloridum corrosivum, 1:1000 to 1:5000 solution; iodoformum.

9. *A diuretic*:

℞ Potassii acetatis.
Potassii bitartratis.
Potassii citratis, āā ʒij.
Aquæ q.s. ad ʒviij. M.

Sig.: One tablespoonful in half a glass of water after each meal.

10. "A *serum* is a product obtained by injecting into an animal, usually a horse, a culture (*e.g.* Diphtheria) or the toxin from a culture (*e.g.* Streptococcus) of the organism. Serums may be subdivided into—(a) *Antitoxic serums*, such as Diphtheria and Tetanus, which are obtained by injecting filtered cultures into the animal used to provide the serum. (b) *Anti-bacterial serums*, such as Anti-Streptococcus and Anti-Gonococcus, in the preparation of which unfiltered cultures are used. Serums are usually injected in the flank or between the shoulder blades, the skin having previously been cleansed and the syringe carefully sterilized. Cases are on record where they have been given intravenously with normal saline solution and also per rectum.

"A *vaccine* is a finely divided suspension of killed cultures of a microorganism which is injected directly into the human subject. The object is to stimulate the individual to elaborate his own antibodies, which results in increased resistance to the ravages of bacterial infection. Vaccines are of two kinds—(a) *Autogenous*—prepared from the organism isolated from pathological material taken from the patient. (b) *Stock* prepared from virulent cultures of the organism, isolated from other cases of similar bacterial origin. Vaccines are administered by subcutaneous injection by means of an all-glass hypodermic syringe. The site of injection may be the flank, thigh, shoulder, or back. The skin is first sterilized by a pledget of cotton wool saturated with a suitable antiseptic, *e.g.* lysol.

"Briefly, the difference is that with a serum the opposing influence to the toxins is produced outside the human body, while with the vaccine it is produced inside and the degree of immunity conferred is greater with the latter than the former. It should also be noted that the dose of a serum is much higher, from the standpoint of the amount of fluid injected, than in the case of a vaccine. With the former the dose usually ranges from 10 c.c. to 50 c.c., while with the latter it is, as a rule, not more than 1 c.c." (*Holland's Pharmacy Handbook.*)

THERAPEUTICS.

1. *Flexible collodion* is used as a protective application, also to prevent bedsores, seal wounds, close punctures made by aspirators. *Cantharidel collodion* is used as a blistering agent.

2. *Boric acid* is a feeble disinfectant; in dilute solution it is antiseptic and soothing to mucous membranes; it is used as a dusting powder and in lotion and ointment in cases of ulcers, eczema, wounds, burns; in cystitis it may be used to wash out the bladder; it is also used as a disinfectant in conjunctivitis.

3. *Salicylic acid* is used externally as an antiseptic; internally, it is given for rheumatism, migraine, gout, sciatica, cholelithiasis. It is a specific for rheumatic fever. It is generally given in the form of sodium salicylate, but the lithium, ammonium, and strontium salts are also used.

4. *Sodium bicarbonate* is an odorless white powder, with a salty taste, soluble in 12 parts of water, insoluble in alcohol. It is used as an antacid, antipruritic, and analgesic; internally, it is sedative to the stomach, but in large doses it stops the gastric digestion. Given after meals it relieves hyperacidity of the gastric juice. It is *incompatible* with acid substances, heavy metals, and alkaloidal salts.

5. *Spiritus ætheris nitrosi* is a transparent liquid with a peculiar penetrating odor and a sharp and sweetish taste; it is inflammable. It is used as a diffusible stimulant; it is also diaphoretic and diuretic and slightly antipyretic. Dose 15 to 60 minims.

6. *Ethyl chloride* is a gas at normal temperature and pressure, but it is usually supplied condensed into a liquid which is volatile, colorless and inflammable. It has a pleasant ethereal odor. It is used as a general anesthetic in short operations where ether is not desirable. It is not so safe as nitrous oxide, and is followed by headache and vomiting. It does not relax the muscles. It is said to give rise to erotic sensations.

7. *Alumen* is alum, a crystalline solid, of sweet and astringent taste, and acid reaction; soluble in about ten parts of water, freely so in glycerin, insoluble in alcohol. It is used as an astringent and styptic, and is useful in stopping bleeding from the nose, gums and superficial cuts. The *exsiccated alum* absorbs more moisture, and so is somewhat caustic as well as more powerfully styptic, and has been found useful in bleeding tooth cavities, hemorrhoids, and soft corns. Internally alum is used as an astringent mouth wash or gargle; also as an emetic.

8. *Arsenic trioxide* is antiseptic, irritant and caustic; it causes inflammation, severe pain and necrosis of tissue; it is used as an aid to digestion, in dyspepsia, in the vomiting of alcoholism or pregnancy; in anemia and leukemia it increases the number of the red cells; it is a general tonic and improves the appetite, digestion, bodily vigor and body weight. The *liquid preparations* are: Liquor acidi arsenosi, liquor potassii arsenitis, liquor sodii arsenatis, liquor arseni et hydrargyri iodidi. All of these liquid preparations (except the liquor potassii arsenitis) can be administered with acids.

9. *Hexamethylenamine* is a crystalline solid without odor, and of a sweetish taste. It is readily decomposed by acids and by heat, is insoluble in ether, slightly soluble in alcohol and in water. It is used in infections of the genitourinary tract, bacteriuria, typhoid, infections of the gall-bladder and in cerebrospinal meningitis. Its action is due to the splitting up of the compound, and the release of formaldehyde. The danger of large doses lies in the fact that the patient may suffer from frequent micturition, hematuria, pain in the bladder, irritating urine; sometimes the kidneys may be irritated; headache, skin eruption and gastric irritation may also follow large doses.

10.

℞ Liquoris potassii arsenitis ʒjss.
Sodii salicylatis ʒv.
Glycerini, ʒj.
Aquæ menthæ piperitæ q.s. ad ʒiv. M.

Sig.: Take one teaspoonful in water, gradually increasing to a dessertspoonful, after meals.

This prescription may be used for cases of diabetes mellitus.

(To be concluded.)

SYPHILIS OF THE NERVOUS SYSTEM.*

BY JOHN A. FORDYCE, M.D.,

NEW YORK.

PROFESSOR OF DERMATOLOGY AND SYPHILOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, NEW YORK.

THE number of patients who show involvement of the spinal fluid in the secondary period of syphilis bears a certain relation to the total percentage of cases with lues of the nervous system. In a series of cases of secondary syphilis examined in my hospital service two years ago less than 20 per cent. revealed abnormalities in the spinal fluid. Recently another series of 63 cases were punctured; 10 showed very slight changes as to lymphocytosis and globulin content, coming well within the borderline cases, while 15 exhibited a definite increase in cells and globulin with a positive Wassermann reaction in 7. Thus 25 per cent. of the cases gave evidence of a definite pathological condition of the cerebrospinal axis, while 16 per cent. showed trifling abnormalities. The significance of the latter we are not prepared at this time to state, but it may be assumed that they are only transient and part of the systemic affection.

The standard used was a cell count over 5, a globulin content demonstrated by the Pandy test, a positive Wassermann reaction in amounts to 2.0 c.c. of fluid, and the color changes elicited by the Lange test. Statistics in the literature treating of abnormal fluids in the secondary stage of lues are variously quoted at from 10 to 90 per cent. In criticism of this disparity, it is possible that too much significance has been attached to minor changes as increased pressure, increase of a few cells or a trace of globulin. My belief is that only such individuals who show very conspicuous changes as evidenced by a definite cell count, globulin and positive Wassermann are candidates for one or the other of the different clinical types of cerebrospinal syphilis and that in a large majority of patients the spirochaetae must be destroyed spontaneously or by therapeutic agents administered in the ordinary way. It is said that from 9 to 25 per cent. of all syphilitics develop disease of the nervous system. These figures have little value at present as they were compiled before the era of laboratory diagnosis and must be revised on the basis of more exact data. With our modern aids of diagnosis we are in a position not only to differentiate the specific from the non-specific types of disease but also to make the diagnosis of syphilis in many cases that would otherwise go unrecognized.

Our greatest hope in the cure of syphilis of the nervous system lies in the adequate handling of the infection in its early inception. In other words it must be prophylactic. Failing this, too great stress cannot be laid upon the early recognition of signs or symptoms which point to involvement of the cerebrospinal axis. The syphilographer and dermatologist by contact with cases of secondary syphilis are in a position to discover the earliest clinical signs of involvement, such as irregularity of the pupils and irresponsiveness to light, exaggeration of the knee jerks, headache, auditory and ocular defects, or oculomotor paralyses. These are all positive indications for lumbar puncture. If dermatologists and genito-urinary surgeons were familiar with the earlier manifestations of nerve involvement they would uncover many cases of nervous syphilis against which a therapeutic attack could be made and the patient rendered secure from future degenerative changes.

The treatment in the early active stage must be intensive and systematic and should consist of a combination of salvarsan and mercury, for we have learned that salvarsan alone is apt to be followed by neuro-recurrences. It has also been shown that in patients inadequately treated a pleocytosis, marked increase of globulin and a strongly positive Wassermann reaction may be present without evincing any subjective discomfort, the condition remaining latent for years until symptoms of tabes or paresis make their appearance. When these cases are clinically developed irreparable damage has already been done to the nerve tissue. It is therefore incumbent upon the syphilographer to treat the fresh infection energetically and wherever practicable to examine the spinal fluid at the completion of the treatment or, in the absence of physical signs, after a provocative injection of salvarsan which should be given one year after the Wassermann reaction has been continuously negative.

In the treatment of luetic affections of the nervous system it is important to properly instruct patients that the procedure is a long drawn out one and unless they are willing to place themselves under the care of a physician for one or two years it is hardly worth while to undertake it. It is true that the progress of certain types can be arrested by intravenous therapy alone combined with mercury and potassium iodide. I have had under observation for the past five years cases of cerebrospinal syphilis of the basilar meningovascular type where salvarsan was administered only intravenously and the fluid findings have become negative, the symptoms have disappeared, and there has been no relapse. In a few cases of tabes and optic atrophy the condition has been brought to a standstill and even shown marked improvement. This method, however, is inadequate for the great majority of sufferers for I have repeatedly seen patients who have had 10 to 15 intravenous injections of salvarsan with the pro-

*Read before the fortieth annual meeting of the American Dermatological Association at Washington, May 8, 9 and 10, 1916.

longed use of mercury and potassium iodide with little or no change in the fluid findings or clinical symptoms. After a course of subdural injections both symptoms and serological findings greatly improved.

Chart I—Spinal Fluid Findings in Early Secondary Syphilis.

In outlining the course to be pursued I have found the best procedure to be the following:

In patients with a negative blood and a positive fluid a provocative injection of salvarsan should be administered and the Wassermann reaction taken at stated intervals. If it remains negative subarachnoid treatments may be begun at once. When both blood and fluid are positive two or more injections of mercury should precede the intravenous administration of salvarsan and after two or three doses of the latter the intraspinal injections instituted, supplemented by the intravenous. In paresis my usual practice is to begin the intraspinal injections after the first intravenous treatment. The intervals between doses, and this applies to both routes of introduction, are regulated by the reaction produced in the patient. Where subdural injections are well borne they may be given in series of four to six one to two weeks apart with a rest period of four to six weeks and then another course. Frequently tabetics are met with in whom intraspinal medication cannot be repeated oftener than once a month.

Since the introduction of the intraspinal method in 1912 by Swift and Ellis we have treated in my private work and at the Vanderbilt Clinic 110 cases of tabes, 13 of taboparesis, 12 of optic atrophy, 25 of paresis and 20 cases of other types of cerebrospinal syphilis. At first the original method of Swift and Ellis, namely, the use of auto-salvarsanized serum was adhered to; for the past two years the modification of Ogilvie with the direct addition of salvarsan to the blood serum. In the earlier work it soon became apparent that salvarsan in quantities of one, two or three milligrams often acted as an irritant and caused traumatic irritation of the lower cord which manifested itself in bladder paralysis, numbness of the gluteal region and extremities with an increase in the ataxic state. Some patients bore these large amounts of the drug without apparent injury and even marked improvement in their symptoms, but we felt that the risk was too great to justify their continuance. The method, however, seemed a logical one and if a therapeutic quantity of the drug could be used which would accomplish the desired result short of an irritating effect it was well worth a thorough trial. The reasons for employing this technic instead of the auto-salvarsanized serum recommended by Swift and Ellis were, first, that a definite quantity of salvarsan can be introduced and the dose more easily controlled; second, the addition of a definite amount of the drug with a smaller quantity of serum, and third, the possibility of preparing several doses with the blood serum removed from a single patient. The last is of decided advantage in treating a large number of hospital patients. Then, too, the intraspinal injections often have to be repeated more frequently than the intravenous injection and in cases with a negative serum there is no indication for the latter. Experience has shown that the blood serum removed indifferently from patients acts equally as well as the autogenous serum. The most important step in the technique, besides absolute asepsis, is the use of a salvarsan solution which is nearly neutral. The blood is removed from an arm vein and is centrifugalized, the serum pipetted off and then centrifugalized again to insure complete removal of any red cells. To 8 to 10 c.c. of this serum 1 20 to 1 2 milligram of salvarsan according to indications is added. This mixture is incubated at 37 C. for 40 minutes and inactivated at 56 C. for one half hour.

As to dosage, patients with general paresis tolerate larger doses than those suffering from tabes or other forms of cerebrospinal syphilis. For tabetics the initial dose should be 1 20 to 1 10 milligram, depending on the bladder involvement and the amount of pain present. The quantity is gradually increased; in some patients never exceeding the dosage of 1 10 milligram; in others 1 5 or 1 3 milligram may be injected without producing much discomfort. The intervals depend upon the reaction and vary from ten days to a month. In paretics the primary dose may be $\frac{1}{4}$ milligram running up to $\frac{1}{2}$ milligram and repeated at intervals of a week to ten days to two or three weeks. In patients in whom the cord is not involved weekly injections of $\frac{1}{4}$ milligram have not produced any irritative symptoms. There is apparently no limit to the number of in-

jections that can be given. An activation of the lesions after the first injection is not a contraindication to the use of the drug but calls for care.

The reactions incident to the treatment of nervous syphilis fall under two headings: (*a*) Those dependent upon the intravenous injection and (*b*) those occurring after intraspinal medication. The majority of patients, providing small initial doses are given, preceded by two or three injections of mercury, are able to take the intravenous treatment without bad effects. Patients are met with from time to time, however, who from the first do not support it well even in small doses. They become actively ill an hour or two after treatment, with chill and vomiting and complain of malaise for the next day or two. A woman with paresis and a man with tabes under observation had this type of reaction each time they were treated. A reaction of an anaphylactoid nature characterized by flushing of the face, rapid breathing, with cardiac or thoracic oppression is also seen in a certain number of patients. More rarely severe reactions are encountered with alarming symptoms as chill, fever, headache, and mental excitability succeeded by coma. Several years ago I noted such a reaction in a patient with cerebrospinal syphilis. In two or three days he entirely recovered and subsequent treatment was well tolerated. Another patient who had a hemiplegia several years before and who at the time under discussion was being treated for choroiditis and atrophy of the retina, became unconscious three days after an intravenous injection of 0.35 gm. of salvarsan. He regained consciousness after several hours but was disoriented, mentally confused, and unable to speak. The next day he was normal. As part of the intravenous treatment an intensification of the lancinating pains, girdle sensation, or bladder symptoms is not uncommonly met with in tabes if a large dose is administered. With the exceptions noted reactions can usually be obviated by keeping well within the dosis tolerata for that particular patient, if necessary making the intervals a little shorter in order to get the desired effect.

days, and is relieved only by the recumbent position. Usually it can be avoided by rest in bed for forty-eight hours after treatment, but occasionally patients suffer in spite of this precaution. Rarely vomiting as an isolated symptom comes on two or three hours after treatment and lasts until the next day.

Of the second group by far most of the discomforts occur in tabetics and usually manifest themselves as exacerbations of their lancinating pains, gastric or rectal crises. They appear within a few hours, last for a day or so, and are often severe enough to require the administration of opiates. These paroxysms are then followed by longer intervals of freedom from pain. It is well to bear this type of reaction in mind and to give very small doses for the first few treatments as its severity is often proportional to the size of the dose. Since we have been using 1/10 to 1/8 or even as low as 1/20 milligram patients have complained of less inconvenience. Alcoholics and morphine habitués tolerate both intravenous and intraspinal treatment very poorly as a rule. Among the severer types of reaction bulbar symptoms sometimes make their appearance, that is, shock with marked laryngeal crises, irregular respiration and partial loss of consciousness. In a paretic this train of symptoms developed each time after the first three injections, becoming less intense and then ceasing altogether. He is now treated with amounts of 1/5 to 1/4 milligram without any discomfort. It is interesting to note that his first intravenous treatment was followed by mental confusion. In another case, a woman with general paresis, aphasia and mental confusion lasting several hours developed two days after the fourth intraspinal treatment of 1/10 milligram. There was no paralysis. In yet another case a fatal hemorrhage ensued within twenty-four hours after the introduction of ¼ milligram. The patient was a man, aged 47, markedly alcoholic.

From the foregoing it will be seen that while in the larger percentage of cases there is little risk attending either intravenous or intraspinal treatment in disease of the nervous system it is not altogether a harmless procedure and it cannot be emphasized either too strongly or too frequently that every precaution be carefully carried out in regard to preparation, size of dose and sufficient rest in bed after treatment. Whether in the subdural injections the untoward effects mentioned are due to the irri-

The reactions following subdural injections form two groups: (1) Those incidental to puncture, and (2) those due to the medicated serum itself. In the first class belongs chiefly the headache which sometimes develops twenty-four to forty-eight hours after the treatment, coming on shortly after the patient gets up. It is very annoying, lasts several

tating action of the arsenic or to a change in pressure acting on the diseased vascular walls cannot be positively asserted.

The results of the treatment may be grouped according to their effect on the biological findings and the clinical status of the patient. Cure, amelioration, or failure is dependent upon the extent and type of the morbid process, *i.e.* whether an active meningeal inflammation is present or degeneration of the essential nerve structures. While the same physical signs may be produced by both processes their prognosis is quite different. Where the symptoms are due to an active inflammation with strongly positive fluid the outlook is very encouraging. Where, however, the underlying process is one of degeneration with atrophy and sclerosis with negative or weakly positive fluid findings the prognosis is not so hopeful.

Of the laboratory findings the pleocytosis is most susceptible to therapy and usually disappears after a few injections; in many cases with intravenous treatment alone. The Wassermann reaction and the globulin content are more refractory, the latter persisting even after the Wassermann reaction has become negative. The influence of treatment on the Wassermann reaction in the fluid depends upon the type of the affection met with. In cerebrospinal syphilis it is more quickly affected by the combined treatment than in tabes or paresis. In some cases 13 injections intravenously and 1 injection intraspinally brought about a reversal. In others 16 intravenously and 15 intraspinally were required. Treatment should be continued for a time in spite of a negative reaction as I have seen it become positive again after several months where it had been intermitted with the first negative findings. In tabes with the reaction positive with 0.2 c.c. or less of fluid it is usually very slow to disappear but gradually grows weaker under prolonged treatment. Its persistence is suggestive of taboparesis. This can be confirmed by the colloidal gold test. In taboparesis and paresis the reaction is most resistent; in some cases fixed. In the greater number of cases I have under observation it has only been influenced in the higher dilutions remaining ++++ with 0.4 or 0.6 c.c., even where 30 to 40 or more intraspinal injections have been given. In a few cases the reaction has become completely negative to 2.0 c.c., the globulin has been reduced to a trace and the colloidal gold test has been changed from a paretic to a luetic curve. These in my experience are exceptions. In one case where the serological findings have become practically negative the patient has steadily deteriorated clinically. The gold sol reaction usually runs parallel with the other findings and changes from a luetic curve to normal in cerebrospinal syphilis and tabes, and from a paretic curve to a luetic curve, rarely normal, in general paresis and taboparesis.

The clinical achievements may be summarized as follows: In active progressive tabes the lancinating pains are ameliorated or disappear entirely. The gastric and rectal crises are usually controlled or regress and the ataxia is markedly decreased and in some cases has disappeared. Disturbances of sensation partially or completely clear up. Spincter control and sexual power have improved or returned to normal. The patients feel better, put on weight and are able to resume their occupation. I have noted no return of absent reflexes. The following cases are illustrations of the therapeutic results obtained:

Case I.—Tabes; man (40). Syphilis eight years ago. For one year severe pains in legs, girdle sensation, and marked ataxia; absent reflexes, Argyll-Robertson pupils. Blood ++++; cerebrospinal fluid (3/11/13): Cells 70, globulin ++++, Wassermann ++++ to 0.4. Treatment, 12 intravenous; 10 intraspinal injections. Patient could not take mercury and was unrelieved by intravenous treatment. Under subdural therapy leg and girdle pains disappeared. He is able to walk without assistance, has gained considerably in weight, and for two years has been back at his work. Serological findings have remained negative.

Case II.—Tabes; man (32). Syphilis fourteen years ago. Tabetic symptoms four years. Loss of coordination; most pronounced ataxia; lancinating pains, rectal and vesical control impaired. Blood ++++. Fluid (2/10/12): Cells 34, globulin ++, Wassermann ++++ to 0.2 c.c. Treatment, 15 salvarsan injections intravenously; inunctions and injections of a soluble mercurial salt. Result: Freedom from pain; spincter control regained; sexual power improved; most marked change in ataxia, which is now scarcely perceptible, and patient is able to walk several miles a day.

Case III.—Tabes and optic atrophy; woman aged thirty-two. Syphilis probably fifteen years ago. For four years severe headaches; manual incoordination and slowly progressing numbness. For two years girdle sensation and ataxia. Reflexes absent; marked Romberg; gait very ataxic, patient almost unable to walk. Eight months before treatment vision of left eye became impaired and then failed entirely. Right eye showed irregular pupil, sluggish to light and accommodation; fundus slightly pale, vision 40/20. Blood Wassermann ++++, spinal fluid cells 67, globulin ±, Wassermann ++++ to 0.4. Treatment, 19 salvarsans intravenously; 16 mercuries; her last salvarsan injection was given 7/24/14 and the last mercury 1/5/15. The latter drug she did not tolerate well. In March, 1915, she gave birth to a child. She was seen again on April 27, 1916; a most remarkable improvement in her gait had taken place; only a very slight ataxia remained. The condition of her right eye has remained stationary. Her general health is very much better and she has gained 12 pounds in weight.

Case IV.—Tabes; man aged forty-one. Syphilis

nineteen years ago. For two years has had rectal crises. Knee jerks normal; station good; bladder slow; sexual power weak; pupils unequal and sluggish to light. Blood Wassermann ++++. Spinal fluid: 150 cells, globulin ++, Wassermann ++++ to 0.4; Lange: luetic curve. He has had 11 intravenous and 9 intraspinal injections of salvarsan in dosage of 1/10 to 1/5 milligram and two courses of mercurial injections. Excepting a trace of globulin his serological findings are negative; his blood remains ++++. The crises which were intensified by the first few intraspinal injections have cleared up entirely.

Case V.—Incipient tabes; man, aged forty-three. Syphilis twenty years ago. Was first seen January, 1911, at which time he exhibited the symptoms of incipient tabes. Two years before he had had double vision. His serum was ++++. His fluid examination on November 21, 1912, showed 14 cells, positive globulin, negative Wassermann. Serum, negative. Treatment, 10 intravenous injections of salvarsan and several courses of mercurial treatment. Clinically the pains which had been a pronounced symptom have entirely disappeared. The patient was again punctured April 27, 1916, and showed a normal spinal fluid and a negative blood.

The results in optic atrophy depend upon whether the nerve substance is primarily affected or whether there is an extension from the meninges. In primary optic atrophy the essential tissue it attacked either by gummata or Huebner's arteritis (Nonne). It is, however, more often affected secondarily and the vast majority of cases show positive findings in the fluid with symptoms of tabes. In the former treatment at first appears to be effective in arresting the process but some cases slowly progress in spite of the apparent improvement. In the secondary form energetic treatment is especially indicated and gives a more encouraging prognosis.

Case VI.—Optic atrophy; woman, aged forty-eight. Syphilis six years. One year after infection double vision and strabismus. When seen in October, 1912, vision of right eye 20/50; left, fingers at 4 inches. Cerebrospinal fluid: Cells 24, globulin +, Wassermann ++++ with 1.0 c.c. She has had 23 intravenous injections of salvarsan, 1 intraspinal, several courses of mercurial injections, inunctions, and mixed treatment. Under treatment her headaches ceased; vision in right eye was 20/20, and in left, fingers at 2½ feet. August 21, 1914, the report on her eyes was as follows: Vision of the right 20/20, of the left, fingers at 5 feet. The condition has remained stationary and at the present writing the fields of vision are normal in the right eye and somewhat improved in the left. The paleness of the left disc is apparently about as before.

Case VII.—Optic atrophy; man, aged thirty-five. Syphilis denied. June, 1911, blurring of left eye; pupils irregular, sluggish to light and accommodation; both discs pale, left markedly so. Vision of left 50/20, right 40/20. Spinal fluid October 6, 1912: Cells 15, globulin ±. Wassermann —; serum ++++. Treatment, 17 salvarsan injections intravenously, several courses of mercury and mixed treatment. February 16, 1915, ophthalmologist's report read as follows: Accommodation has increased in both eyes; vision has improved; the irides react to the stimulus of light but they are a little sluggish. Optic disc improved somewhat in color and fields of vision improved.

Case VIII.—Optic atrophy; man, aged fifty. Syphilis denied. Gonorrhoea twenty-five years ago. In June, 1914, complained of pains in legs and double vision. Disturbance in walking; slight headache. Impairment of vision of right eye, 20/70 —. Blood ++++. Spinal fluid: 0 cells, globulin +, Wassermann ++++ to 0.8; Lange: luetic curve. Treatment, 3 intravenous, 12 intraspinal injections of salvarsan besides mercury. The patient feels better in every respect, his mind is clearer, he has no pain, and no fatigue after exercise. The vision in this right eye is now 20/30. Spinal fluid: 12/1/15 cells 2, globulin +, Wassermann ++ with 1.0 c.c.

Summarizing the cases of paresis, all showed the typical biological findings; namely, a positive serum; an increase of cells varying from 18 to 290, strongly positive globulin content and a positive Wassermann in dilutions of 0.2 or less. The colloidal gold test gave a typical paretic curve, that is, complete decolorization in the first four to eight tubes. The number of intraspinal injections administered varied from 6 to 41 alternating with intravenous injections of salvarsan.

In the following abstracts are cited the average type of case met with and from these can be gauged the hope to be held out for amelioration of the condition:

Case IX.—Paresis; man, aged 38. Syphilis in 1902. No symptoms until 1912, when he complained of headaches. No treatment. In April, 1914, mental symptoms with marked excitability and grandiose ideas developed and he was placed in an institution. On February 20, 1915, he came under my care. His serum was ++++; spinal fluid: cells 290, globulin ++++, Wassermann ++++ to 0.05; gold reaction paretic curve. Since that time he has had 23 intravenous and 25 intraspinal injections of salvarsan, inunctions and intramuscular injections of mercury. In June, 1915, a marked improvement in his mental condition had taken place, he was able to leave the sanatorium, and the treatment was then carried out on the ambulatory plan. In August, 1915, he seemed normal mentally and went back to work. His fluid became normal as to cells, globulin remained strongly positive, and Wassermann positive to 0.4; the Lange showed a luetic instead of the paretic curve. His remission lasted until July, 1916, when he became careless about his work in the office, destroyed letters, and exhibited kleptomaniac tendencies.

Case X.—Paresis; man, aged fifty. No history. Mental symptoms began the early part of 1912. May 8, 1914, serum ++++; spinal fluid: cells 48, globulin ++, Wassermann ++++ to 0.2; gold test positive. He has had 15 intravenous and 24 intraspinal injections of salvarsan. Clinically, he has not returned to his former mental condition but is able to remain with his family, takes part in their social affairs, goes to the theater, etc. In other words, for the past two years he has led a comfortable vegetative existence and excepting an increased irritability now and then has had no mental outbreaks. His fluid is normal only as to cells.

Case XI.—Paresis; man, aged forty-five. Primary lesion in 1905 for which he had three years' treatment. In 1904 he developed continuous headaches, was unable to attend to business, became very nervous, disconnected and rambling in his talk. May 13, 1914, blood ++++, spinal fluid cells 30, globulin ++++, Wassermann ++++ to 0.05; goldsol, paretic curve. He received 12 intravenous injections and 20 intraspinal injections from ¼ to 1 milligram. The first few injections were followed by short periods of improvement during which his mental condition cleared up somewhat but never returned to normal. The latter treatments produced no change whatever and in April, 1915, he developed attacks of weakness, became progressively feebler until the latter part of June, when he died. Serologically there was only a reduction in the cell count.

Case XII.—Paresis; physician, aged thirty-eight. Chancre 1904. No treatment. In July, 1914, change in personality. Wassermann at that time ++++; grandiose ideas, filthy habits, forgetful. Spinal fluid: August 23, 1914, cells 180, globulin ++++, Wassermann ++++ to 0.05, colloidal gold reaction positive. Had 30 intravenous injections of salvarsan, several courses of mercurial injections, and 41 intraspinal injections from ¼ to ½ milligram. His mental improvement was quite marked after the second intraspinal injection and progressive improvement was noted until the latter part of March, 1915, when he had a severe headache; became talkative and excitable, with grandiose ideas and delusions, some disturbance of speech, memory very poor. Under continued treatment this phase passed over. He went about his ordinary affairs, attended lectures and clinics, and had a remarkable insight into his condition. Excepting a tendency to become easily excited and quarrelsome, with two attacks of transient aphasia, his remission lasted nearly a year. On February 22 of this year he had an attack of aphasia which did not clear up, and two days later a hemiplegia. He died on the 26th. A post-mortem was not obtained.

In estimating the results obtained in the treat-

ment of paresis the benefit to be looked for, it seems to me, depends on the duration and the anatomical involvement. In the type with the preponderant changes in the meningo-vascular structures with a high cell count, a rather sudden onset and marked mental disturbance, good results can be obtained and the process perhaps kept stationary. Where the parenchymatous tissue is chiefly involved with atrophy or sclerosis, attended by a low lymphocytosis, and an insidious onset, the degenerative changes have probably advanced too far and at most only temporary improvement can be expected with almost certain relapse. No one can tell when paresis begins and by the time it is clinically manifest the damage is irretrievable. Cases that respond to treatment and those where therapy yields but indifferent or no results give the same gold reaction with decolorization in the paretic zone. We have, therefore, in this test not a means of distinguishing possible different types but a method of separating true paresis from forms of meningo-vasculitis which simulate it.

While a promise of cure cannot be held out in cases which are clinically developed, the treatment is of value in inducing remissions, making the patients socially possible and amenable to home care and in a few cases restoring them partially, at least, to economic efficiency. If the diagnosis of paresis can be established through the colloidal gold reaction when the affection is in its incipiency we may be justified, perhaps, in speaking of a cure.

Conclusions.—In order to develop a successful plan of treatment in syphilis of the central nervous system it is necessary to have a clear idea of how infection takes place. In the secondary period of the disease about 25 per cent. show marked changes, while a lesser number reveal slight abnormalities in the spinal fluid. We conclude, therefore, that a certain percentage of such cases are cured spontaneously or during the general treatment of the disease. It is impossible to estimate the number of syphilitics who later develop manifestations on the part of the nervous system but it is probably larger than the statistics show. A careful examination of affected individuals would probably reveal a larger number with abortive or rudimentary tabes or paresis or involvement of the fluid without objective signs.

All patients at the end of the first year of their infection should be punctured whether or not they have manifestations or positive signs of the disease. If the fluid remains negative to all of the tests they can be assured with a reasonable amount of certainty that they are not menaced by the possibility of a later development. Furthermore a positive colloidal gold test with a persistent positive Wassermann in the high dilutions points to an impending paresis whether or not the patient shows mental impairment. In other words, years before the stigmata of degeneration appear the pathological process is at work in the central nervous system. When the clinical symptoms of paresis develop like memory, speech, hand writing defects, etc., the disease has already existed for years. This statement also applies to tabes. The results obtained in the treatment of tabes would seem to confirm the hypothesis that this affection is primarily an inflammatory process involving the meninges rather than a degenerative process, for if the latter assumption were correct we could not hope to derive benefit from the treatment.

\ West Seventy-seventh Street.

PRESENT METHODS OF EXCRETA DISPOSAL IN RURAL SCHOOLS.

A SERIOUS MENACE TO HEALTH.

By J. A. NYDEGGER,

BALTIMORE, MD.

SURGEON, U. S. PUBLIC HEALTH SERVICE.

Every American child is entitled to the best that we can give him in everything—good food, good clothing, a good home, good training and teaching, good sanitary school houses and environs—to fit him to grow up into a healthy citizen well equipped to fight the battle of life. When we fail to provide these we fail in our public duty—we fail to give the child a square deal—the square start in life. We give him a handicap, we start him in life with the worst possible handicap he could have—a poorly developed and poorly nourished body, with lessened resisting power to the inroads of disease, and sooner or later he falls an easy prey. It is, therefore, of the very highest importance that those who have to do with the rising generation of children should have uppermost in mind that the greatest asset of a State is its healthy citizens, and that unless we do provide proper surroundings and safeguard the children with all these precautions, we cannot expect the children to grow up into healthy adults.

Formerly we were taught that the country is more healthful than the city, but recently the sanitarians have called attention to the fact that the death rate in the cities is falling more rapidly than in the rural districts. The cause of this is simply a matter of sanitation. While sanitary provisions have been made for the cities, the rural sections have been neglected. When the country was first settled, the population was scattered, the virgin soil was not polluted, and the water was pure, and many of the communicable diseases, which now claim thousands, were practically unknown.

How frequently have we heard the country district schools spoken of as the bulwark of the nation, and yet how little has apparently been done for the public schools of the rural communities? In the cities and larger towns the schools are, as a rule, fairly well administered, and the buildings are fairly well constructed and equipped in accordance with hygienic measures, but how about the sadly neglected rural schools? When we come to the question of hygiene in the rural schools, this is one of the supreme questions of the hour, I take it.

It is highly important for us to understand that these schools are provided for that part of our population which is peculiarly susceptible to the influences of bad hygienic surroundings. It is a sad fact that the schoolhouses in many of our rural communities are far from sanitary. The majority of the rural school children spend from 25 hours to 30 hours weekly in the schoolroom for a period of several months each year for 8 to 10 years. Such being the case, the need of hygienic schools, environs, and a good personal hygiene must be admitted.

The filth and foul air of the toilet rooms of many schools in decent town communities are at times unspeakable, but if we venture into the remote rural districts we are wont to observe rather frequently the total absence of this important sanitary accommodation of the schools, and the scholars responding to the daily calls of nature must make use of whatever privacy is afforded by objects or irregularities of the ground surface in the vicinity of

the buildings, with necessarily resulting soil pollution, and the great liability of dissemination of disease germs contained in the excreta thus deposited on the ground. In this manner pathogenic germs may and do easily gain access to the source of supply of the drinking water for the school, and illness, many times of a serious nature, results from the use thereof.

The dangers of the drinking water are thus twofold: from the impure water and from the common drinking cup, still so obviously in use in the rural schools. Numerous instances are on record where typhoid fever has been spread in schools in this way.

The unscreened and unprotected privy constitutes a grave and serious menace to the health of any community. Sooner or later it is bound to become the depository of typhoid and at that moment it becomes a hazard to every resident in the vicinity, for that very environment has created an insect host and otherwise capable of disseminating the scourge to every point of the compass.

The water supply of the rural school generally comes from a shallow well or surface spring. Drinking water coming from such a well is liable to be more dangerous than that from a spring, as it is frequently located very near the school building, and is more liable to receive surface drainage from the vicinity of the school, the outhouses, if any, and consequently it is more likely that it will be polluted and its use will be a greater risk to health.

Hookworm is another plague of the rural schools of the Southern States. In the South many of the country school children go barefooted, and the young hookworm or larva gains entrance to the body, usually through the skin of the unprotected feet, and after a circuitous route through the body finally reaches the alimentary canal, and attaches itself to the wall of the bowel, and feeds and grows to mature size. It is not the loss of blood, as is popularly supposed, that causes the severe anemia, paleness, and other symptoms in the victim of hookworm infection, but the toxin introduced into the system by the hookworm. These sufferers are pale, and appear bloodless. Many deaths result from it in the warm, semitropical, and tropical countries all around the world. This disease is disseminated by means of human excreta, containing the eggs, reaching the ground.

In some rural schools in the United States, the surveys made by the Public Health Service have shown that from 82 to 98 per cent. of the children were suffering from hookworm. In other schools the infection of children with hookworm has been shown to be as low as 10 to 12 per cent.

Hookworm is not the only intestinal parasite found in school children, the eggs of which, reaching the ground soil in the excreta, are disseminated by wind, dust, hands, feet, flies, hogs, dogs, fowls, and birds, and gaining access to water and food, after having undergone development to the larval stage, again enter the body and produce diseases. Chief among these are the *Amœba histolytica* or *tetragena*, the cause of dysentery; *Balantidium coli* and *Trichomonas*, causing diarrhea; *Oxyuris vermicularis*, *Ascaris lumbricoides*, *Trichuris trichiura*, and *Hymenolepis nana* or dwarf tapeworm, which produce intestinal troubles. The direct effect of these infections on the child, aside from other bad effects, is reflected in physical dwarfing and mental retardation. Especially have these conditions been observed in school children, as shown by studies made in those ill with the ineffection by the Public Health Service.

The Rockefeller Sanitary Commission, in the course of its surveys, found the rural schools a marked factor in producing diseases. In the case of 46,748 school children examined, who were harboring intestinal parasites, 22,782, or 48 per cent., had hookworm infection; 7,991, or 20 per cent., had ascarides; 2,915, or 15 per cent., had *Trichocephalus dispar;* 1,246, or 18 per cent., had dwarf tapeworm; 134, or 0.2 per cent., had *Strongyloides*, and 48, or 0.09 per cent., had *Oxyuris*.

Of most interest is the fact that many of the cases of ascaris infection presented marked symptoms of mental retardation and anemia.

The Public Health Service, in an extensive survey of sanitary conditions, in from 1,200 to 1,300 rural schools, conducted in 13 States, with the examination of some 175,000 school children, during the past three years, has shown that in the territory covered there is a general lack of sanitary supervision in the construction and maintenance of rural school buildings and outhouses, and of medical supervision of the pupils. In the course of these investigations we failed to find the installation of a scant dozen of sanitary privies for the use of rural school children.

Recent investigations conducted by the writer showed in 66 rural schools in Indiana that only 6 outhouses out of 132 were in good sanitary condition, while 42 were in fair condition, and 84 were in bad sanitary condition. A more recent survey of the schools of Manatee County, Florida, also conducted by the writer, showed a somewhat better sanitary condition of the privies in the urban schools as also in the 11 rural schools visited. Here, out of the total number of outhouses examined, 6 were found to be in good sanitary condition, 2 in fair sanitary condition, and 14 in bad sanitary condition. The results as shown by these two surveys with respect to the insanitary condition of the outhouses will serve as the standard of index of the insanitary condition of outhouses at all of the rural schools inspected by the service during the aforementioned period. A description of one of these outhouses will practically apply to all, as also the insanitary conditions found to exist about them. The majority of these wooden buildings are simply set upon the surface of the ground, with no attempt at closing them up beneath or at the back to prevent the free access of domestic animals and flies, and they were noted in all stages of deterioration—from newly constructed to dilapidation. The majority of these outhouses were found to be in a horrid condition. In many the conditions were unspeakably dirty and insanitary, being filled with excreta almost to the seat. In a considerable number of the outhouses objectionable odors were so strong as to make it practically impossible to remain within. Almost 50 per cent. of the outhouses were found to be without screens in front of the doors, and at many schools the outhouses for the boys and girls were placed near each other on the premises. At some schools they were placed near each other on the premises. At some schools they were built double for the use of the two sexes, and some of these double outhouses were noted to have no screens in front of the doors. In a few outhouses a urine trough had been provided for boys, while in others the seats and floors were urine soaked, and the odor of urine was all-pervading. In some instances an attempt to suppress the strong arising

odors by the use of lime was noticed. In a very few instances was it observed that any attempt at cleaning up and removal of the excreta had been made at the beginning of the school year, or in fact at any time.

The question may, therefore, be asked what is the real method of excreta disposal at rural schools, which, in the main, are provided with outhouses, as have been described. The answer is a very simple one—no method, but a trusting to luck and nature's elements. The excreta are allowed to accumulate in the most of instances until the space below the privy seat is filled to overflowing and conditions become intolerable. Then the outhouse is removed to another spot near by, a few shovelfuls of earth or none at all, usually the latter, are sprinkled over the accumulated excreta of years, and the same process is gone through with again until the privies are again filled and require further removal.

What is happening in the meantime? Aside from the dissemination of disease-producing bacteria and parasites by flies, animals, fowls, and other means there is an infiltration of liquid excreta, rain, and urine washings from the excreta on to the surface and into the soil constantly going on, with the result that in the course of time the surface as well as the subsurface water becomes polluted, and there is percolation of any pathogenic organisms that may be present in the excreta, through the subsoil into the water of the shallow wells or springs, frequently located, as our surveys have shown, dangerously near the outhouses. How great is the danger of pollution of the drinking water of rural schools in this manner is strikingly shown in some instances observed during these surveys. At one school the source of water supply, a shallow dug well, some seven or eight feet deep, was noted as being but sixty feet away from the nearest outhouse, and the natural drainage of the outhouse was directly toward the well. There was grave danger of the pollution of the drinking water from the outhouse, which was in a highly insanitary condition. At another school, the well, a shallow driven one, eighteen feet deep, was found to be located less than 100 feet from the two outhouses, with natural drainage toward the former. These houses were found to be in bad sanitary condition with years of accumulated excreta on the ground beneath them. The outlet from the outhouses was an open, shallow ditch, and infiltration of sewage into the soil along the whole course of the ditch was constantly going on, with constant danger of percolation of disease-producing organisms through the subsoil into the water of the well.

Glaring instances of indecency, as also grave danger, were noted during these surveys, through the privies having been located in close proximity to the school buildings. In one such instance it was observed that the privy, a highly insanitary one, by actual measurements, was but eight feet distant from an open window of the schoolroom, thus allowing the malodors from the privy to permeate the air of the room, and in addition offering an excellent opportunity for flies, which having fed on the possible germ-laden excreta but a few feet away, to transfer the infection to the food of the school children. Numerous other instances of a similar nature and equally as hazardous were noted.

The above are but instances of what was constantly being encountered during these surveys, showing the wide extent of dangerous negligence that exists to-day in rural schools in the United States.

The remedy for this menace to the health of the children of the public rural schools is not hard to find, but is difficult to apply, by reason of the fact that competent medical inspection of schools is still in its infancy in this country. True, it is that in our larger cities, and in some of the smaller ones, as also in a few rural communities, there is a regular medical inspection of the schools, but in the vast majority of the latter such a thing as medical inspection is still unknown.

In many sections of the United States the sanitary conditions surrounding many rural schools are scarcely other than medieval. Because of the absence of a privy, or almost equally as bad, a privy where the excreta are deposited on the ground soil, pollution of those places will spread disease to the pupils, and the infection may be carried to uninfected homes. An immediate and radical reform in the sanitary surroundings of these schools is urgently needed. If sanitary privies were used and intelligently supervised at the rural and urban schools there would be an immediate and marked reduction of hookworm disease, typhoid fever, and many other diseases produced by intestinal parasites.

In a word, a great step forward will have been accomplished when sanitary conditions surrounding the schools are improved to a point where the country school will not form—what it is to-day—the great disease-spreading center for rural and semi-rural communities.

Such as I have described are the insanitary conditions too often found in our everywhere neglected rural schools—among the school children of the people of our own land and of our own blood, of Anglo-Saxon lineage and intelligence.

It is no mere dream to describe here, though briefly, "The Country School of To-morrow." The little red or white one-room one-teacher school, about which we heard so much, located here and there, to the extent of a dozen or even more, in a single township, will be replaced by one consolidated school, placed as near the center as possible, and for the more distant pupils a daily to-and-from conveyance in groups will be provided. For the school ample grounds, of many acres, well laid out and beautified, with recreation grounds, will be needed. The building will be modern in every respect, and will represent the latest appliances in school sanitation and equipment, fireproof, roomy, of attractive architectural design, an excellent building, kept in excellent sanitary condition throughout, provided with well heated, properly lighted and ventilated class and recitation rooms, laboratories, agricultural and domestic science departments, manual training, music, with gymnasiums, showers, sanitary toilet rooms, with crematory or water sewage excreta-disposal facilities, and a large and attractive assembly room; and the school, in addition to being the educational center of the township, will be also the social improvement center of the community. These forces will then be working in harmony for the better education and greater uplift of the community, affording better health and greater happiness, and all for the creation of better citizenship, for a better State, and a better country.

Cause of Death in Intestinal Obstruction.—Snow concludes that neither starvation nor bacterial activity is responsible for death in intestinal obstruction, but that a toxic substance exuded from the duodenal mucosa is the cause of the lethal symptoms. Subcutaneous saline infusion prolongs life by replacing the fluids lost by vomiting and diarrhea.—*N. Y. State Journal.*

THE ECONOMIC VALUE OF SPEECH CORRECTION.*

By IRA S. WILE, M.D.,

NEW YORK.

As man is essentially a social animal his speech is probably his most important social characteristic and activity. As the main instrument of intercommunication, its full development is essential for the fullest evolution of human relations. While writing is valuable for self-expression, speech alone serves to promote spontaneous self-expression through thought utterance.

The political economist might object to the title "the economic value of speech correction" on the grounds that speech is not wealth, but merely one of the means of acquiring wealth. Technically speaking, value is a power which an article confers upon its possessor of commanding in exchange for itself the labor or the product of labor of others. The degree of efficiency of labor depends upon many causes, including the physical organization and the mental equipment of the laborer. However, regardless of the capital invested in speech improvement, the social economist will hardly deny that health, intelligence, and the power of communicating ideas are essential and better than wealth and are paramount phenomena in promoting the activity of man in acquiring and making just use of his wealth. Correct speech is not necessarily an essential in the acquisition or utilization of money, but adds a tremendous force for living well and wisely.

From the standpoint of the school, speech correction is indicative of the centering of thought on the education of children rather than upon the importance of the subjects taught. It is a new manifestation of the idea that educators must consider the subjects whose minds are to be developed as of equal importance to the subject matter to be taught. Obviously, the most vital phase of speech improvement lies in the organization of elementary school instruction and methodology, so that bad speech habits may be checked during the school life of children. The prevention of speech defects, in so far as slipshod teaching is responsible for them, is a large field which has scarcely received adequate cultivation.

Recognizing the social economic value of speech, it is patent that the attainment of fluent unimpaired habits of speaking represents a distinct gain to the community. The value, therefore, of speech correction would be represented by the saving to the community of expenditures now involved as a result of existent or future speech defects. It is exceedingly difficult to establish with even approximate mathematical precision the economic cost of speech defects. In this country, data are not available to determine the total number of persons suffering from speech defects. The economic importance of speech defects depends upon the functional ability of individuals, and at various ages the importance of speech defects varies. It is obvious that the importance of a speech defect in a child of 5 is less than in a man of 20.

Speech defects cannot be considered as isolated phenomena. There are no reliable estimates of the number of individuals suffering from speech defects without the complication of an organic or functional derangement such as further decreases the economic value of an individual. Speech defects among the deaf and the feeble-minded, for instance, constitute only a portion of the potential weakness of the individual and their speech defects therefore can be considered simply as a part of the general disability lessening the economic worth of the afflicted.

All speech defects represent abnormalities. In a wide sense abnormal children are "those afflicted with anything whatever that unfavorably affects their lives in relation to the social medium in which they live." Consequently speech defects represent abnormalities which *per se* limit the possibilities of children and adults to realize to the utmost their potential power for uniting in the activities of the world.

In the London County Council report of 1909, there is presented an investigation of 19,303 children showing 1.95 per cent. to have speech defects and 1.3 per cent. to be stammerers. Rouma reported in the children of Belgian cities 11.5 per cent. with speech defects and 1.4 per cent. stammerers. Conradi, in 1904, studied 87,444 children in American cities and found 2.46 per cent. among them with speech defects and 0.87 per cent. to be stutterers. On this basis, there would be in our American schools over 500,000 with speech defects and at least 200,000 stutterers. Some defects such as lisping are known to decrease as school life progresses, while stuttering increases while children are in the classroom. This represents the field of activity whose economic value we are to consider. In general, the ratio of boys to girls possessing speech defects is as three to one. The total number involved is in excess of the number of blind and deaf in our population and fully equal to the number of mentally defective children and insane.

Speech defectives and particularly stutterers are likely to be backward and even retarded in their school work, although there are many who maintain excellent position as measured by ordinary standards of school progress. A large proportion of stuttering, probably 50 per cent., could be prevented by adequate provision for improvement in methods of school instruction. A large proportion of the stutterers are curable. The limitation of the stutterer is marked, not so much in his powers of acquisition and appreciation as in his ability to give verbal expression to his thoughts. His mentality may be intact but his opportunities for giving evidence of his mental power are hampered by virtue of his explosive expression which deprives him of an attentive audience. Frequently he may be regarded as stupid or dull when he is suffering from sensitiveness, self-consciousness, embarrassment, or anxiety because of his affliction. Attempts at speech improvement likewise are of service in detecting early organic disorders of cerebration and may at times lead to the prevention of irrational extravagances.

Speech improvement in schools is productive of the saving which may be secured through preventing what Fletcher of Clark University referred to as "the leakage of energy" on the part of both teacher and class, which ensues during the attempted recitation of a stutterer. Systematic speech improvement classes save the time of the teacher and the class. They promote more rapid progress and secure more concentrated attention upon the subject matter being taught by preventing the diversion of attention to the peculiarities of the individual child reciting. To this extent, they

*Read before National Educational Association, New York City, July 6, 1916.

are productive of a monetary saving in the cost of teaching, though mathematically this would be difficult to estimate.

It is patent that the average sufferer from a speech defect is deprived of his fullest opportunities of education and self-expression. This is manifest, particularly, in those unfortunates who are actually willing to be deemed dull and backward rather than suffer through reciting; and under ordinary circumstances the very act of recitation increases and tends to protract the disability.

The various types of speech defects which are dependent upon malformations, such as harelip, cleft palate, hypertrophied tonsils and adenoids, and dental deformities reveal an economic loss which must include the cost of operations, nursing care, and hospital treatment. While speech improvement classes will not tend to reduce these expenditures, they will save valuable time by securing prompt attention to them. Unfortunately, permanent defects may result even after medical and surgical aid have been afforded, but under these circumstances the potentialities of the sufferers are less circumscribed than before and their activities in occupations may be encouraged to a greater extent than was previously possible.

The majority of speech defects are combined with defects of vision, hearing, and muscular coordination, or cerebral mal-developments. Of the twenty million children in this country it has been estimated that five per cent. have impaired hearing and twenty-five per cent. have impaired sight. It has been adjudged that some impediment in speech exists in three per cent. of the school children. There is no differentiation, however, in so far as I have been able to ascertain, as to the nature of these various impediments.

The character of speech defects and their importance varies according to the degree of deafness. Mutism results if deafness occurs before speech is developed. This subject however is beyond our present interest.

Studies in speech correction may indicate in numerous instances that stuttering has been increased by the attempt to make sinistrals dextrals; and the speech defect thus resulting may actually serve to impair the industrial progress of the child for the sake of securing uniformity in classroom methods. Experience in our own schools has demonstrated that stuttering and lisping children may be restored to normal speech and participate with naturalness and greater effectiveness in the work of their classes.

In Germany, investigation has shown that of the 15,000 children in special schools for defectives, 6 per cent have associated speech defects. It is thus obvious that the economic importance of speech defects is bound up in considerations of the importance of such causative conditions as feeble-mindedness, deafness, and neuropathic manifestations.

Assuming that estimations by Van Sickle, Witmer, and Ayres are correct in that 4 per cent. of our public school children are feeble-minded, it would mean that there are 800,000 feeble-minded children in the United States, although it must be appreciated that of this number 100,000 are genuinely mentally deficient and should be treated in institutions instead of public schools. If, then, investigation should show that the German percentage, 6 per cent., would apply to all our defectives, there would be in the United States forty-eight thousand defective children with speech defects. Ninety-four cities in the United States have special classes for defectives, 46 make special provision for the deaf and semi-deaf, and 3 have classes for stammerers, stutterers, lispers, and the dumb.

The economic cost of speech defects is registered in the limitations of occupations that are available for individuals who have speech deficiencies. The more pronounced the defect, the more limited the field of activity. Few employers desire deaf-mutes and their industrial situation is most difficult. Law and medicine, or even the ministry, are opened occasionally to those talented individuals who have risen above their speech limitations and have been able to submerge their sensitiveness and self-consciousness. Their self-expression depends upon what they have to say rather than the way they say it.

Where feeble-mindedness is the basic condition, the occupation is naturally limited by the scale of intelligence to which the individual child can rise. In the New York Institute for the Deaf and Dumb, instruction is given in the shoe shop and tailor shop, while carpentry, printing, gardening, and similar occupations are made available. State institutions for the deaf and dumb require 5 to 7 years of training at a per capita cost of three hundred and twenty-five dollars per year. It has been estimated that one in every twenty-four hundred of the population in the United States is a deaf-mute. This would indicate that there are about 37,500 deaf-mutes in the United States. This would mean that the mere cost of education in the State institutions for all of these deaf-mutes cost approximately twelve million dollars per annum. How few are taught to speak! We cannot actually cure blindness, nor mutism, nor idiocy.

Recognizing the industrial limitations of those suffering from speech defects and appreciating the obstacles to professional life, their undesirability as teachers, their handicaps as physicians, their limitations as pleading lawyers, and their impossibility as preachers, it is but natural that we should seek to preserve or secure their potential utility by restoring them to normal speech function. To what extent can this possible economic loss be prevented? In the experience of the elder Gutzman in 46 German cities, 72.7 per cent, of stutterers were cured, 23.6 per cent. were improved, and in only 3.7 per cent was there complete failure. Dr. H. Gutzman found 89 per cent. cured, 9 per cent improved, and in 2 per cent. failure. Coen, in Vienna, cured 60 per cent, improved 30 per cent., and had only 10 per cent. of failures. Chervin claims that success is almost certain if the general conditions are favorable and fulfilled. Under such circumstances, failure to promote speech improvement is an indication of indifference to or ignorance of the possibilities of reclaiming to full usefulness victims of this speech derangement.

Another economic gain is to be secured through speech correction in the prevention of industrial accidents. The relation of speech defects to the cost of industrial accidents has been hinted at in those reports which attribute a part of the accidents to the inability of employees to speak the prevailing language of the factory, mine or shop There are numerous positions where quick utterance is required and in which stuttering might and does jeopardize the lives of fellow workmen in times of emergency.

The importance of discouragement, anxiety, family distress, embarrassment, diffidence, and shyness upon the development of high moral character cannot be estimated. Wherefore, among delinquents speech deficiencies are noted with greater frequency than among the normal population. This may be due possibly to the fact that there is a greater amount of feeble-mindedness among delinquents and the speech defect is coincidental. If speech correction can prevent any children from moral degeneration, its economic usefulness is enhanced.

The relation of speech defects to normal delinquency has not been determined, although it is possible to appreciate that speech defects, if interpreted as closely related to mental abnormality, probably play some part in the problems of delinquency. It is apparent that self-expression through speech is a most important factor to constitute the mental defective a social asset. It is doubtful if the cost of securing this result can be segregated. It would be unfair to guess at an allowance out of the computed costs of educating the feeble-minded.

In the ordinary public school system, the educational cost for correcting speech defects has not been estimated. A special teacher is necessary, an ungraded class is important. The development of normal speech must be facilitated through personal analysis of the underlying causes of the speech deficiency. It is vitally important, both for the benefit of the individual child with a speech defect and for the rest of the children in the class, that special classes for stutterers, stammerers, and lispers should be maintained with a view to developing normal speech for them.

Finally, in estimating the economic importance of speech defects, I can but repeat what I have already stated. The actual cost of speech defects to society cannot be estimated at the present time in dollars and cents. The limitations of self-expression is a loss to the individual and to the community. Speech defects which interfere with the fullest expansion of consciousness along the lines of culture and industry are anti-social. They decrease the social worth of the individual and rob the community of the full fruits of human mentality. They retard and pervert economic power.

In conclusion, I can but suggest that the work of speech improvement now scarcely begun must make tremendous gains during the next few years. The monetary expense is negligible in view of the possible gains to society. School systems should recognize that it is part of their function to develop to the full the latent possibilities of school children. This is impossible while we are neglecting a single type of those handicapped in learning. In the education of mental defectives, society can scarcely be repaid for the cost of education because so much of it is now spent upon those who will never be able to make adequate economic returns. In the case of speech defectives, particularly in the case of stutterers and lispers, this state is reversed. The improvement of speech defectives enhances both their economic and social value. Well may we paraphrase the statement of Dr. Caroline Yale to the instructors of the deaf, "The plea now should be not for more speech but for better speech." The plea should now be for more speech, for better speech, and for the prevention of speech defects.

230 West Ninety-seventh Street.

TREATMENT OF INOPERABLE CARCINOMA BY BIPOLAR IONIZATION.*

By G. BETTON MASSEY, M.D.,

PHILADELPHIA.

While the unipolar method of ionic destruction remains a most valuable agency for the immediate eradication of small epitheliomas of the skin and mucous membranes, 93 per cent. of this classification having been reported as cured by this method in a somewhat recent communication to the Philadelphia County Medical Society,† grave cases of carcinoma and sarcoma have of late been placed by the writer under an improved bipolar technique, permitting of more thorough and more controllable destruction, and with a material lessening of the time during which the patient is under anesthesia.

In the bipolar technique the active needles are inserted just beyoud the peripheries of the growth while the indifferent, negative, electrode is inserted in its center, instead of being a pad on a distant body surface, thus confining the current and its chemical and thermic activities to the growth itself and its edges. As no material amount of current traverses the general body structures in this arrangement we are free to push the method to the point of producing a boiling temperature in the larger growths, thus adding the valuable agency of heat to the devitalizing chemical action of the dispersed ions of zinc from the erosion of the zinc electrodes attached to the positive pole. Both positive and negative electrodes are made of zinc, but the positive only for the electrochemical purpose of being dissolved into ions and dispersed throughout the growth. The negative electrodes are made also from sheet zinc for mechanical reasons, since thin plates of this metal may be readily cut by shears into self-retaining corkscrew, fish-hook, or crab's claw shapes for attachment to the center of the growth.

Heat alone is the destructive agency in both the diathermy and the Percy methods of treatment of cancer recently introduced. In the author's method, as outlined above, heat is merely an addition to the electrochemical destructive process, and is invoked only in large growths when heavy currents are needed. In small growths the ionization alone is sufficient, applied in the unipolar method; and so simple is this variation of the method that any physician who has the ordinary direct or galvanic current in his office has no excuse for permitting small epitheliomas of the skin surface to grow large from neglect, as he can destroy them in a few minutes by easily devised electrodes.‡

The following unpublished cases, in which the major bipolar ionization was employed, illustrate the varied technic demanded at times:

(303) Mrs. ——, aged 67, was referred by Drs. Rimer and Clover, of Clarion, Pa., September 23, 1913. Enjoying excellent general health, a lump had appeared on the scalp behind the right ear about eighteen months before, which had been removed by excision in December, 1912, the pathologist examining the specimen, pronouncing it carcinoma. Three months later recurrence was noted. On admission to the Sanitarium a growth the size of a horsechestnut emerged from the scalp

*Read before the American Electrotherapeutic Association, September 13, 1916.

†Ionization Treatment of Cancer; End Results of Twenty Years' Work.—*American Journ. Surgery*, September, 1914.

‡For further details of method, see "Ionic Surgery in the Treatment of Cancer," by G. Betton Massey, New York, A. L. Chatterton Co., 1910.

slightly posterior to the scar of former operation. It was firmly adherent to the underlying structures, apparently including the periosteum, and was beginning to break down. In the upper portion of the neck there was an enlarged gland, the size of a marble, situated at the posterior edge of the occipital insertion of the sterno-mastoid.

September 26, 1913. Under chloroform a bipolar ionization was done, a number of fine zinc needles being inserted beneath the growth and connected with the anode, and with the cathode attached to its center, a current of 500 milliamperes was gradually turned on. Infiltration with the ions occurred rapidly and complete devitalization was apparently complete in four minutes, when the current was turned off. Two minutes of maximum current of the same strength sufficed for the gland, with the needles similarly applied.

The sloughs separated duly under diluted zinc oxide ointment; but three months later, January 22, 1914, two more nodules were found, nearly as large as the original recurrence, just beyond the edge of the scar. A second major bipolar application was made at this time similar to the first, except that a current of 700 to 1000 milliamperes was used for a total of seven minutes.

The high malignancy and wide spread of the cell colonies was shown in this case by a third major bipolar ionization under ether being needed two weeks later, when 500 milliamperes were used for thirty minutes. The final resulting slough revealed a small portion of the outer table of the skull denuded. The healing of the wound appeared to be assisted by phototherapy, and the patient was discharged finally from the sanitarium to the care of home physicians three weeks after the last ionization. At this time there was a sinus leading to the periosteal denudation. A scale of bone separated spontaneously later under the ointment, permitting final healing of the wound from the bottom.

A letter dated April 20, 1916, states that the patient continues free from evidence of the disease.

(311) A farmer, aged 39, was referred by Dr. C. L. Clover, of Knox, Pa., August 14, 1914. The patient had had increasing nasal obstruction for years. Six months ago the right nostril became entirely obstructed and discharge and odor appeared, both of which were steadily increasing. One month ago the hearing also became impaired. He has had no severe pain. On admission the voice was nasal and choked, the hearing was impaired in the right ear, and there was a pronounced cancerous odor. Visual inspection of the anterior nares showed the posterior portion of the right nasal cavity obstructed by a smooth neoplasm. Visual inspection by the mouth showed little; but the vault of the pharynx, when cocainized, was readily explored by the forefinger and middle finger inserted behind the soft palate, palm upward. This procedure revealed a large growth the size of a lemon split in half attached to the vault by a slightly constricted base, the attachment extending further on the right than the left and involving the right Eustachian opening. The free surface was cauliflower-like, eroded, and bled freely on touch. No enlarged glands were found at this time. A specimen removed at operation was pronounced carcinoma.

August 15, 1914. Major bipolar ionization was employed under ether with the following technique: Three long, slender zinc electrodes, readily curved, with their soft rubber coverings, to a shape that would permit their inch-long bare tips being passed up behind the soft palate and into the base of the growth, parallel with the vault, were attached to the positive pole. A single negative, suitably insulated to near the tip, was then inserted into the growth through the right nostril, and a current of 500 to 1,000 milliamperes was gradually turned on and maintained for twenty-eight minutes. Considerable heat developed. The separation of slough and healing of wound were uneventful, and followed by improved breathing and voice.

Five months later, January 9, 1915, the patient had a clear voice and the site of the growth when explored with the finger showed a healthy cicatrix. A large, movable growth was discovered in the neck below the ear at this time, being apparently composed of a group of infected cervical glands beneath the edge of the sternomastoid muscle. A major bipolar application was made at this date with needles passed through the skin and beneath the growth, the negative being attached to the skin above it. A current of 1,000 to 1,100 milliamperes was employed for fourteen minutes. The slough came away in due time without hemorrhage, and appeared to include the whole of the affected group of glands. In May the scar was excellent, and appeared free from disease.

In August, nevertheless, a little over a year after the first application, a consultation with Dr. Clover revealed an even larger group of infected glands deeply seated in the neck, and it was decided that the external carotid should be ligated before another attempt at ionic destruction. A cutting operation was objected to by the patient, however, and the ionization was begun by the use of 1,000 milliamperes bipolar, under ether, for two minutes, it being the intention that this should be followed by minor applications after the separation of the slough. Severe secondary hemorrhage supervened on the fifth day, followed by death from repeated hemorrhages on the seventh day.

(331) A hardware clerk, aged 51, was referred by Dr. Omar Morgner of St. Charles, Mo., October 13, 1915. His general health had been good in spite of convivial habits until one year ago, when a carcinoma of the right side of the base of the tongue and floor of the mouth was diagnosed. Competent surgeons in St. Louis declined to operate. On admission, the left half of the tongue was found to be indurated beyond the middle line from tip to base, with a deep erosion on the lateral surface that was continuous with an equally extensive erosion on the right side of the floor of the mouth. The posterior edge of the growth extended to the fauces. He could swallow liquid food only. Pain in the tongue and in the left temple was constant. Two submaxillary glands were enlarged and protuberant.

Oct. 14, 1915. Under general anesthesia Dr. Warmuth ligated the external carotid artery, the operation being followed immediately by a bipolar application with active electrodes passed through the tongue just beyond the indurated portion, the completeness of the fixation being guided by a rubber-gloved finger in the pharynx; other electrodes were passed beneath the lower portion of the growth, and still others just beyond the buccal edge. These electrodes were insulated except the portions actually inserted in the tissues. Retracting the lips with a miniature lamp covered with a slender test tube and with a hard rubber retractor, a negative electrode was placed in the center of the growth and a current of 1000 milliamperes was turned on and maintained for thirty minutes. A boiling temperature accompanied the usual chemical effects. Destruction of the glands was postponed until the ligation wound had healed. The patient was fed through a stomach tube during convalescence. A week later the glands were destroyed by a bipolar application of 200 milliamperes under local anesthesia.

In December and January additional minor applications were made to remnants of disease in the floor of the mouth. The patient's condition being greatly improved, save for persistence of the neuralgic pain in the temple, he was sent home, but returned later showing increasing growth at the upper portion of the buccal edge and increasing pain. This growth caused a bulging of the cheek in the parotid region.

April 26, 1916. Major bipolar application of 500 to 1000 milliamperes for 30 minutes to the buccal growth in the parotid region, all electrodes being passed into the growth through the oral opening, with the lips retracted as before. The immediate result was a flattening of the distended cheek and parotid region and disappearance of the neuralgic pain that had hitherto been unaffected by the treatment. During the separation of the slough there was a severe hemorrhage, apparently from a reestablished collateral circulation, which was controlled by pledgets of cotton wet with Monsell's solution. Further active treatment was abandoned June 9, 1916, as there was distinct evidence of disease below the scar of the ligation wound in the neck, and the patient was sent home in a temporarily improved condition.

(332) J. F. L., aged 72, real-estate dealer. About Dec. 1, 1915, a small, whitish growth was found on the under side of his tongue by his physician, Dr. D. W. Levy of Philadelphia, who called in Dr. Franklin Brady, chief surgeon to the Roosevelt Hospital. At Dr. Brady's suggestion the patient was referred for ionization as he hesitated to excise one half the tongue on account of the patient's age, and of the further fact that the patient was then under treatment for a growth within the bladder which had caused several severe vesical hemorrhages.

January 3, 1916. There is a proliferating epithelioma on the under surface of the right side of the tongue,

near its middle, about 2 centimeters in diameter. No enlarged glands could be found. A minor bipolar application, that is one under local anesthesia, was carried out as follows: With the tongue held in extension by the operator's left hand encased in a sterile lisle thread glove to ensure a good but painless grip, the area beyond the growth was carefully infiltrated with a 2 per cent. solution of quinine and urea hydrochloride. At the end of seven minutes small zinc needles, sixteen in number, were inserted concentrically beneath the growth and a bipolar application of 200 to 350 milliamperes was made for eleven minutes, without material pain.

May 24. Scar in tongue perfect. No sign of disease. Patient has had another vesical hemorrhage and is in bed.

June 3. Patient died of uremia due to bladder trouble.

1823 WALLACE STREET.

THREE CASES OF ACUTE ANTERIOR POLIOMYELITIS TREATED SUCCESSFULLY BY TRANSFUSION OF CITRATED NORMAL BLOOD OF ADULTS.

BY G. A. RUECK, M.D.,

NEW YORK.

I NEVER had had any patients suffering with acute anterior poliomyelitis and I knew the first and later symptoms of this disease only from books. Naturally I had seen patients after they had been crippled for life and when they were trying to diminish the effect of the abated disease by orthopedic treatment. Nevertheless, I was fortunate enough to be able to make an early diagnosis of the cases to which I was called when the epidemic of acute anterior poliomyelitis started this summer in New York City. But after the diagnosis was made it was rather discouraging to think that there was no curative treatment known and that even physicians who were considered to be authorities in the scant study of the virus could only make suggestions in regard to the treatment of this disease. Every suggested remedy had to be tried first and, strange to say, normal blood and its serum was declared not to be curative.

The serum of patients having recovered from an attack of acute anterior poliomyelitis and injected into the spinal canal, as suggested by Dr. Simon Flexner, seemed to me a rational remedy and has since given some good results, to judge from the reports in the lay and medical press in cases where it has been used in the Willard Parker Hospital and in hospitals which imitate its treatment. But not being connected with a hospital where anterior poliomyelitis cases are gathered together from the entire city although they are by no means all treated with blood serum, I should have had the greatest difficulty in procuring the blood and I should have needed first-class laboratory facilities in order to prepare the serum. These facilities I did not have. Besides the preparation of the serum would have taken too much time. But help had to be brought early and quickly before the large motor cells in the spinal cord and brain of my patients were completely destroyed, as nerve cells never can be replaced, and as we never can know in advance whether a patient will be killed or crippled by this disease or whether he will entirely recover. Complete recovery is a matter of chance and we should take no chances in such a serious disease. Then I wanted to help quickly before the Board of Health could take the children to an isolation hospital where they are kept comfortably in bed but where in the beginning nothing was done to cure them. I decided to treat my patients by transfusion of blood taken from healthy adults and prepared according to my method (reported in the MEDICAL RECORD, February 27, 1915 and April 15, 1916), with 2 per cent. sodium citrate solution. The reasons for this treatment which I used before the Board of Health began with the serum treatment, were the following:

1. Most healthy adults and children are immune to acute anterior poliomyelitis.

2. The blood of most people must contain antibodies or it must at least be able to produce antibodies rapidly when the virus tries to invade the body.

3. If most normal adults and children would not have any protective elements in their blood they all would contract the disease in case of an epidemic.

4. The transfused blood reaches brain and spinal cord quickly by way of the blood current.

5. The transfused blood is a ready food for the tissues (the nerve cells included) and the sick organism does not have to use up its energy to elaborate this blood from the ordinary nourishment passing through the alimentary canal and it can use this energy to fight the disease.

6. The method of transfusion of blood of adults seemed to me superior to the method of injection of serum of convalescents into the spinal canal of sick children, as there must be different strains of the virus just as in epidemic cerebrospinal meningitis. And as Dr. Flexner's polyvalent serum of cerebrospinal meningitis is not curative in all cases of the disease for which it is made, so the serum of people having suffered with acute anterior poliomyelitis which contains antibodies for only one strain of the virus cannot be curative in all cases. Besides we get in whole blood the action of the injected phagocytic cells.

7. People having been sick with acute anterior poliomyelitis are defective in some way or other. Naturally their whole blood or serum, the protective element against one strain of anterior poliomyelitis not counted, is inferior to that of normal adults.

8. Whole blood of adults is a protective agent and acts at the same time like a vaccine in most, if not in all, infectious diseases of children.

My cases were the following:

CASE I.—Kenneth S., Jamaica, 5 years old, of Swedish descent, weighing about 45 lb., was taken ill July 2, 1916. He had headache, chills, and vomiting. After the action of a cathartic he seemed to be well the following three days. In the evening of July 5 he had a high fever. July 6 his temperature was in the morning 104° and in the evening 105.4°. He was treated for "poisoning of the stomach" and received within two days seventeen enemata of two quarts each. The temperature during this time was about 104°. On July 8 he had muscular twitchings of the entire body, especially of hands and feet. July 9 he was delirious, drowsy, very restless during the night, and had a high fever. I saw the boy the first time July 10 at 2 P.M. His pulse was then 96, regular, of low tension and small volume; the temperature per rectum was 101° and the respiration 40 to 45. His eyes reacted to light and accommodation. The tonsils were not inflamed and the nostrils not obstructed. The tongue was heavily coated, the posterior half of its dorsum being brownish. The lips were dry and cracked. Heart and lungs were negative. He was drowsy, had a stiff and painful neck, and a painful back. The right side of the face and the right arm were slightly paralyzed. He could move the right fingers and the forearm, but could raise the upper arm only to the height of the shoulder. The left arm was normal. Left leg: reflexes present, ability to raise the leg is decreased—can stand on left leg. Right leg painful; he can bend but not extend the toes. All re-

flexes except the plantar are absent. Can raise the thigh to an angle of 45° to the body, cannot stand on right leg. Sphincters normal. Skin reflexes present. Skin clammy, of a bluish hue, no eruptions.

The cerebrospinal fluid, sent to the Board of Health and reported on a few days later, showed a few white cells, a slight reaction for globulin and a very slight reaction of Fehling's solution. July 11 at 1 A.M. he received a slow transfusion of 350 c.c. of maternal blood in 2 per cent sodium citrate solution (4 parts of blood and 1 part of solution) into the resected left median basilic vein. The amount of blood transfused was equal to 1211 c.c. in an adult of 150 lb. body weight. After the transfusion the boy had a slight cough, belching of gas, and an evacuation of the bowels. The feces were thin, brown, and offensive. He was talkative, conscious, and felt much better. At 8 A.M. he asked for food and received a cereal, milk, a soft-boiled egg, and bread.

July 12. Sleeps much and has little appetite. The neck is slightly stiff. The face is normal and the tongue clear. He can raise the right upper arm to the level of the vertex of the head and move it in all directions. The right leg is paralyzed; he can move the toes only. He can move the left toes and foot. The left plantar reflex is present, the knee jerk absent. He can bend the left thigh with difficulty, but not extend it. He was transferred to Willard Parker Hospital. On September 7, I examined the boy in this hospital. He looked bright and had red cheeks. Neck, face, arms, and trunk were normal. The left leg was normal, but the knee jerk was absent. He could stand on the left leg. The right thigh could be moved in all normal directions. The right knee jerk was absent and the right leg from the knee down was paralyzed. He could not stand on the right leg.

In general the outcome is satisfactory, considering the grave infection and the comparatively late date at which the blood transfusion was performed.

CASE II.—Ruth S., a sister of Kenneth S., fifteen months old, still nursed by the mother, became sick July 11 and died July 13. A blood transfusion which I offered to do six hours after the onset of the disease and which would have saved the child was refused by the father. Thirty-six hours after the onset of the disease I found her in a stuporous condition. The right arm was paralyzed. The other extremities were very painful and the neck stiff and painful. The temperature was 104°.

The older brother and the two older sisters of Kenneth S., remained well in spite of the great exposure to the disease.

CASE III.—Willard J., Jamaica, twelve months old, weight 21 pounds, breast fed, of Swedish descent, had for the last two days a high fever, was very peevish, restless at night, and seemed to have pain in arms and legs when touched, but took food. I saw the patient first July 12, at 10 A.M. He had motor paralysis of the extensors of the left thigh and leg. Sensation was present. He could not stand on the left leg. The neck was stiff and painful. He had adenoids and phimosis. The temperature per rectum was 100, the pulse 120 and the respiration 30.

July 12 at 1 P.M., he received 250 c.c. of citrated maternal blood into the resected left median basilic vein. When 200 c.c. were given the bowels moved and he passed gas and urine. The amount of blood injected in this case was equal to 1,786 c.c. of citrated blood in a man of 150 pounds of body weight. After the transfusion was completed he had a slight chill and took the breast. Extension of the left leg was possible. He could put the leg to the floor.

July 14. Extension of the left leg is not quite possible. There is no fever. The boy is playful. There is twitching of the muscles in sleep.

July 16. The boy can walk about twelve steps. Then he gets tired and has to sit down. He can extend the leg. The neck is normal. Appetite, bowels, urination and temperature are normal.

July 19. The boy was taken to the Jamaica New Hospital for Infectious Diseases because the family, not following instructions, had communicated with the child's uncle and his family, whose child was taken ill, too. The boy remained in the hospital eight weeks. He can walk and feels fine. The outcome in this case is a complete cure.

CASE IV.—A boy, patient of Dr. S., 3½ years old, breast fed, became sick July 5, 1916. He had anorexia, fever, was restless, peevish and crying most of the time. He had no appetite for five days, and was treated for malaria. July 6 to 8 he was playing on the street. July 9 he vomited and was feverish. July 9, 10, 11, and 12 the boy had fever, was restless during the night and crying when awake. The legs, especially the left leg, were painful when touched. He was in bed all the week.

July 15 the mother noticed that the boy could not stand on the floor, and that the left leg was flexed. Examination shows that the boy is well nourished, looks bright, has a good appetite, weighs about 40 pounds. He has adenoids and enlarged tonsils, is a mouth breather, and has phimosis. The legs, especially the left, are painful when touched or moved. The left leg is flexed. He cannot put the left foot on the floor and cannot walk. The tendon reflexes of both knees are absent. There is spasticity of the flexors of the left leg, the extensors of the left leg being paralyzed. He cries when sitting on the table and complains of pain in the back and legs, but feels comfortable when the legs are hanging down. The temperature is 99°, the pulse 120, the respiration 30.

July 18. The boy received a transfusion of 300 c.c. of maternal blood in sodium citrate solution into the left median basilic vein. The transfusion lasted one hour and was equal to 1,125 c.c. in an adult of 150 pounds of body weight. July 26. The boy can extend the left leg and walk on it. The blood transfusion was followed by an excellent result in this case.

Conclusion.—The firm belief in the curative action of normal adult blood in acute anterior poliomyelitis which caused me to perform a transfusion on the above three cases in the very beginning of this year's epidemic has been crowned with success.

I am only sorry that circumstances did not allow me to treat a greater number of cases. But the good results with normal human blood serum which are obtained now in the Willard Parker Hospital, two months after my blood transfusions, confirm my statements concerning the curative action of normal adult blood. I consider normal human whole adult blood superior to sera. It is a remedy to cure acute anterior poliomyelitis when used early and to prevent it (I believe) when used before the onset of the disease. Naturally it will be difficult to transfuse all children with blood in order to prevent a new outbreak of an epidemic of acute anterior poliomyelitis and of other infectious diseases of children, but whole human adult blood is the remedy.

633 EAST TWO HUNDRED AND FORTY-FIRST STREET.

THE DISCHARGING EAR.

BY ALBERT BARDES, M.D.,

NEW YORK.

OTOLOGIST AND LARYNGOLOGIST, FLUSHING HOSPITAL.

CHRONIC suppuration of the middle ear is frequently one of the most intractable disorders that we are asked to treat. Thanks to modern methods of dealing with acute ear infections and to the general removal of diseased tonsils, adenoids, and other disturbing nasal affections, running ears are not encountered nearly as often as formerly. There is no excuse for allowing an ear infection to lapse into the stage of chronicity, where its control becomes difficult or impossible. The German Emperor is reported to have a leaking ear which has caused and is causing much annoyance. It started in infancy, at a time when such complaints received but scant attention. To-day the poorest person is able to receive better care for an ear affection than the German ruler received fifty years ago.

Practically all middle ear infections start in the nasal chambers, after an acute febrile disorder, notably the grippe, tonsillitis, scarlatina, or measles.

Surf bathing and the highly popular but pernicious nasal douche are also accountable for many infections.

When a middle ear infection follows a febrile disorder, it usually occurs in the second week, when the febrile attack begins to abate. This is the period of reaction, during which the engorged vessels become relaxed and inflammatory exudate is thrown out. At this stage the systemic vitality is low and resistance to disease is poor. Ear infection after the grippe is especially to be feared, on account of the virulence of the infecting medium and the danger of mastoiditis and cerebral involvement.

The nose and the throat at all times harbor innumerable disease germs. Ordinarily these are kept out of the ear by certain safeguards, which protect the integrity of the middle ear and keep it sterile. It is difficult to infect the healthy middle ear. Experimentally, infectious material can be passed through the Eustachian tube and into the healthy middle ear without inducing disease. The foreign substance is promptly expelled into the nose. When, however, the Eustachian tube becomes involved in the general disorder, its protective influence is in abeyance and the middle ear is vulnerable to attack. Sneezing, coughing, and blowing the nose violently are the acts by which infectious substances are usually forced into the ear.

The middle ear of infants is extremely assailable on account of its nearness to the nose, only a short wide tube separating them. The slightest physical derangement in a baby is apt to react upon the middle ear. The mere cutting of a tooth, an attack of tonsillitis, or a slight intestinal disturbance may be the cause of a serious middle-ear infection. Whenever an infant is ill from any cause in which the distress is acute and the fever is high, it is well to think of the ear. Quite often a physician is puzzled regarding a baby's ailment until the ear suddenly starts to flow and discloses the seat of disease.

Of the disorders of child life, scarlatina is the most destructive to the ear. Under the influence of this virulent streptococcic infection, the drumhead and the ossicles are soon eradicated, unless the infection is speedily combated. Twenty per cent. of the deaf mutes and a large proportion of the people who are compelled to go through life with a disabled ear owe their misfortune to scarlatina. Measles and diphtheria are also answerable for many discharging ears, but they are much less injurious to the hearing than is scarlatina.

A discharging ear usually begins this way. When the middle ear becomes infected it becomes filled with serum or exudate. Frequently the secretion escapes into the nose and no harm results. Nearly every one has experienced the deafness and fulness in the head during a heavy cold. It comes from the fluid within the middle ear. If perchance the fluid is unable to escape into the nose it soon fills the various compartments of the middle ear, including the mastoid cells. In seeking an exit the exudate presses against the drumhead and gives rise to the distressing pain known as earache. It is said that convulsions in babies are more often caused by earache than by anything else. The convulsions are the result of meningeal irritation. Fortunately the suffering of infants is seldom prolonged. Their frail drumhead soon yields to the pressure and breaks. The moment the tension is relaxed, pain and fever cease as if by magic. Occasionally, owing to the presence of scar tissue from former infections, the drumhead is resistant and the exudate is forced to seek another place of exit, which is usually through the mastoid cells. It must be borne in mind that in infants the shell of bone that separates the middle ear from the brain cavity is extremely thin and sometimes it is absent, its place being taken by a fibrous membrane. It is thought that the infecting agent of most cerebral affections in babies enters the skull at this point.

Generally an ear discharges for about a week before it stops. If, however, reinfection occurs, or if the process of repair is interfered with, the discharge may last indefinitely. An ear that continues to discharge longer than a month can be considered a running ear. As a rule, the hearing becomes impaired in proportion to the duration of the flow. The anvil and the mallet are the ossicles that first yield to the corroding influence of the suppuration. The stirrup, the tiniest and most essential of the ossicles, happily resists destruction the longest. Its loss is followed by profound deafness.

The amount and the consistency of aural discharges vary greatly. Owing to the glandular activity of youth, the younger the person the more profuse is the flow, as a rule. Most ear discharges teem with disease organisms. As many as ten kinds of germs have been found in the ear of a single person. The commoner pus cocci are generally found in large numbers in nearly all ear discharges. Even in tuberculous infection of the middle ear, so common in children, the tubercle bacilli are found only at the onset of the discharge, for presently the more prolific and ever-present pus cocci predominate and the tubercle bacilli lose their identity. Furunculosis and eczema of the ear canal often result from the contamination of the aural suppuration. Certain kinds of fungi thrive on the debris of a running ear and impart to it a musty, nauseating odor, which becomes noticeable to the sufferer whenever the wind blows into the ear, or when the discharge drops into the throat. Frequently it gives to the breath an offensive odor. In many instances an aural flow drains wholly into the throat, whence it is swallowed and absorbed. A sallow complexion, malaise, headache, nausea, and diarrhea are some of the consequences of autointoxication from swallowing the pus.

Many individuals have an intermittent aural flow that starts up only when the health is below par, as in the presence of a head cold. It is indicative of latent disease in the middle ear. Whenever a discharge is slight, say a drop a day, it clings to the roof of the canal and spreads out like a fan. A leak such as this is often overlooked, the accumulation being mistaken for hard wax. Generally a slight discharge is more to be feared than a copious one, because it is more readily intercepted. A discharge that is thin and malodorous comes from disintegrated bone and is destructive to the hearing. The presence of polyps or of granulations in the middle ear is also indicative of diseased bone. Blood in the discharge comes from the granulations. Pain in a running ear denotes defective drainage.

In dealing with discharging ears, watch should be kept for cholesteatomatous formations. These may be dangerous. In this condition the moisture in the ear causes the cast-off epithelium to collect about a core or nucleus, like the layers of an onion. Insidiously the augmenting mass destroys everything it comes in contact with. It is capable of perforating the skull as neatly as a drill, although it may take years to do so. Frequently the cholesteatomatous

mass breaks up into a brownish foul-smelling fluid and escapes from the ear.

A leaking ear is such a commonplace complaint that generally it is not given the attention it merits. It is regarded as an annoyance rather than as a disability which is likely to become serious at any moment. Many of the laity believe that it is perilous to stop a running ear. The belief is based on the knowledge that the sudden cessation of an active aural flow is fraught with danger. Recently a case of this kind came to my attention. The ear of a man was filled with an astringent powder to check a slight discharge. The powder, uniting with the discharge, was converted into a hard caked mass which prevented the escape of the pus. Alarming septic symptoms arose which had to be relieved at once.

Quite often the parents of a child with a running ear are advised to leave the ailment to Nature and that eventually it will be outgrown. Such advice is erroneous and even dangerous. Most of the crippled ears that give so much trouble in after years are the aftermath of neglect in infancy. Childhood is the time to apply those preventive measures that are the most brilliant achievements of scientific medicine. There are numberless people with aural defects who place the blame upon their parents. The organ of audition is the most delicate piece of mechanism in the body, not excepting the eye, and like any piece of fine machinery it easily gets out of adjustment, especially in infants. A blow on the head, a fall down stairs, or disease in both ears is liable to cause irreparable damage to the ears in a short space of time. Much of the ear disease of babes that robs them of their hearing is avoidable. All newborn babes are mute, so far as talk is concerned. They learn how to speak by hearing others and imitating them, but if their hearing is gone they remain mute. Even young children who have partially mastered the art of speech and have become deaf soon forget how to talk, and lapse into silence.

Children who are hard of hearing are slow in learning to talk. Many a child, thought to be stupid is really not so, but is hard of hearing. Much of a child's education is acquired through the sense of hearing. When audition becomes an effort, a child soon loses interest in its studies and turns its attention to something less exacting. Naturally it soon falls behind in its work. It is imperative that children's ears be watched and tested with the same care that is given to the eyes. Frequently a child with a leaking ear seems to hear well despite its defect. Inquiry usually shows that the hearing is done with the other ear. Whenever one ear is forced to do the work of both ears it is apt to suffer.

Insurance companies, through their losses, have learned to rate persons with a discharging ear as bad risks. Not only is the health affected, the life is endangered as well, both from disease and from accident. The deafness and the dizziness that attend many discharging ears may place the life in peril if they occur at a time when good hearing and steadiness are required. Persons with a diseased ear should exercise care in swimming. When water gets into the middle ear of certain individuals it causes a dizziness and faintness. Getting water into a diseased middle ear has cost the life of many good swimmers who were thought to have succumbed to cramps.

Running ears are treated with far more encouraging results than formerly, and with simpler methods. The sooner treatment is begun the better. A few words about the prevention of discharging ears may not be amiss. A beginning ear infection can frequently be aborted by means of the ice bag, a mild cathartic, fluid food, and rest. If the pain is severe, one dose of an opiate is permissible. More than this might mask the symptoms. The hourly irrigation of the ear with a warm solution of boracic acid is also allowable. Ear drops and applications in general are apt to be more harmful than beneficial. The ear should be kept clean. An earache should not be permitted to last longer than twelve hours. It is the symptom of an active and perhaps a serious infection, and prompt relief is demanded. It is decidedly unwise to wait for the drumhead to rupture or even to bulge. It is far better to open the drumhead prematurely than to allow the infection to spread. If, on opening the drumhead, no fluid is found, the incised drumhead soon mends and no harm is done. It is needless to state that all work upon the ear should be done under the rules of surgical asepsis.

Many lives have been sacrificed through delay in dealing with a middle-ear infection. Within a short time I saw three persons with meningitis from neglected ears. There are other disadvantages in waiting for the spontaneous rupture of the drumhead to take place. The opening is apt to be faulty. Either it fails to provide adequate drainage or else the drumhead is needlessly lacerated. Such an aperture heals with difficulty, and if repair does take place, the hearing eventually becomes affected, by reason of the intratympanic adhesions.

Never should the drumhead be incised without the aid of a general anesthetic, preferably a whiff of chloroform. This is used both to obviate the intense pain of the procedure and to keep the patient from moving and deflecting the scalpel. The incision should be a free one, not merely a stab. Beginning in the lower posterior quadrant, the incision should sweep upwards and backwards, behind the ossicles and near the rim of the drumhead, ending outwards into the swollen periosteum of the canal. The final sweep has been termed the internal Wilde incision. It depletes and drains the edematous tissue and helps to avert mastoiditis. In the left ear the incision resembles the letter *S;* in the right the letter *Z*.

When an infected middle ear is opened, serum is released, seldom pus. In a few hours the discharge becomes copious and purulent. The more active the flow the better the result. Generally, relief follows the operation. If, however, the symptoms do not abate, it is evident that the infectious material within the mastoid cells is unable to escape into the middle ear proper, and that more drastic measures are required.

Ordinarily the after treatment of an incised drumhead is simply to keep the ear dry and clean. Irrigations should be used sparingly, if at all. Used too freely they keep the drumhead in a soggy state and hinder repair. A saturated solution of boracic acid with the addition of some alcohol makes a good cleansing lotion. A poisonous solutin, such as the bichloride of mercury should never be employed in infants, lest it escape into the throat. The cotton wipe is the best implement for cleaning the ears. The patient can assist the cleansing process by inflating the ear after Valsalva's method.

Regarding the treatment of a running ear, the prescribing of ear drops without first ascertaining

the precise nature of the lesion in the ear, is as unscientific as it is generally unavailing. The use of peroxide of hydrogen is especially objectionable. If it gets into the middle ear it may not be able to escape.

It is useless to attempt to check a discharging ear by local measures so long as reinfection from the nose is apt to occur. It is first necessary to cure the nasal disorder. The removal of diseased tonsils and adenoids in children will do more toward preventing an ear infection and stopping a running ear than anything else will. It is my plan, when removing tonsils and adenoids of a child with a running ear, to supplement the procedure by removing the granulations from the middle ear and freshening the edges of the drumhead. Most running ears are controlled by doing so.

Frequently there is an obstacle in the middle ear which favors the continuance of the aural discharge. To overcome this, it may be necessary to enlarge the opening into the middle ear for better drainage; to sever adhesions in the middle ear, or perhaps remove aural polyps or granulations. Frequently an aperture in the drumhead can be made to close by slitting or by freshening the edges of the perforation or perhaps by placing a piece of paper over the opening. If the middle ear can be kept dry the discharge generally ceases. In the hands of the physician the suction pump and the wick usually accomplish this end.

The local remedies used to control an aural discharge have for their object the stimulation of the sluggish mucosa to healthy action. Quite often a discharge of long standing can be brought under control in a short time by the daily use of an alcoholic solution of boracic acid dropped into the ear. A persisting discharge may require something stronger, perhaps a twenty per cent solution of iodin or else a ten per cent solution of chromic acid. Stimulation by the use of heat after Beers' method of inducing hyperaemia is most useful in certain stubborn cases.

Much of the difficulty encountered in the treatment of these diseases is owing to the fact that the affected parts are out of sight. The tiny attic syringe is helpful in many of these cases.

A decade ago it was hoped that the radical mastoid operation of Stacke would enable us to cure all discharging ears, but these expectations have not been realized. In this operation the various compartments of the middle ear are thrown into one kidney-shaped cavity. Besides, the Eustachian orifice is closed and the ossicles are removed, together with all diseased and cellular bone in the middle ear. Unquestionably the procedure is an invaluable one in selected cases, but generally its performance should be deferred until simpler measures have been tried. At the present time the operation finds less favor than it formerly did. The operation has many objectionable features which are usually withheld from prospective patients. The best statistics of the operation show a cure of but 50 per cent. One-tenth of the persons operated upon finally die of meningitis. Others develop facial paralysis and nearly all eventually lose their hearing. The assertion that the radical operation does not affect the hearing can safely be challenged. Any procedure in which the ossicles are removed and the middle ear is covered with scar tissue is bound to seriously disturb the hearing. In many instances it takes a year or more for this to occur.

A better operation for most cases is the mastoid operation of Schwartze, which provides for the removal of the mastoid cells and establishes a free connection between the mastoid antrum and the tympanic chamber. The ossicles are not disturbed and the better drainage and stimulation generally cause the discharge to cease.

164 West Seventy-third Street.

CLIMATE: ITS USE AND ABUSE IN THE TREATMENT OF TUBERCULOSIS.

By J. B. Fish, M.D.,
Medical Director Jewish Consumptives' Relief Association of California.
Los Angeles, Cal.

Does the tuberculous patient need a change of climate? What factors should be paramount in the climatic selection? Where shall this haven of health be? And—how shall he derive the greatest benefits from it?

These questions give but a glimpse into the haze surrounding the all-important subject of climate. And yet, difficult as is the proper solution of these questions, the lack of discrimination evidenced in deciding them, really is astonishing. Not infrequently the patient takes it upon himself to decide upon the change of climate; or he may follow the admonition of some fellow-sufferer, some misguided friend or neighbor, perhaps the milkman or coalman or any one—in fact, except the proper advisor—his physician.

From time immemorial to the present day—the era of serum-therapy—climate always has ranked high in the treatment of tuberculosis. During this time, it is true, many a drug has earned short-lived fame as a positive cure for consumption. It is equally true that since 1882, when Koch put his index on the tubercle bacillus, many a serum has met a similar fate. But climate has held its own.

And while we feel that the time is not far distant when we shall have a specific for tuberculosis, we must necessarily continue to place our faith in such factors as have stood the test of time. Chief among these are: Climate, rest, diet, general hygiene.

But have all these been accepted without qualification? Hardly. All of us are familiar, for example, with the changes affecting the rest-cure idea. It is not so long ago that the general practitioner urged the tuberculous victim to "Go West and rough it." Then came a sudden swerve in attitude when absolute rest and quietude were deemed essential. And now we are confronted with the experience of Bernstein of England and his followers in Europe and America, who—by subjecting the patient to carefully graduated labor and so inducing autoinoculation—have effected cures even in febrile and advanced cases.

A not dissimilar condition existed, and, for that matter, exists still, in the question of diet. For a time we believed that the intake by the patient of an extraordinary quantity of food assisted materially in combating the disease. This led eventually to the idea of "forced-feeding." To-day, however, we take pains to select a diet applicable to the particular condition of the patient; we make it a point not to abuse the digestive organs; we are careful not to unduly burden the eliminative organs that already are overtaxed by the tuberculous toxins.

So we see how time has wrought changes even in this accepted creed of treating tuberculosis. But climate, considered as an integral factor, alone has held its place in the sun. Why?

It is quite beyond the scope of this article to

detail the reasons that should prompt a climatic selection in any given case or to differentiate between low and high altitudes, cold and warm regions, and their relative advantages in the treatment of tuberculosis. Nor is it feasible here to discuss the various physiological factors involved—such as humidity, precipitation, rarefication, the degree of solar intensity, quickened circulation and respiration, the increase in red blood corpuscles—and their effect on health. Rather will we concern ourselves with the psychological effects of climate, and particularly with the influence it exerts on the nervous system.

For, in tuberculosis, as in any other prolonged disease, the mind as well as the body suffers. But in tuberculosis, particularly, the nervous system suffers doubly. It shares in the morbid effects resulting from the functional disturbance incident to the disease and, in addition, is taxed by the work it must necessarily perform in connection with the recuperative process. The rigid mode of life required of the tuberculous patient subjects the nerves to a form of restraint to which they have been unused and at which they naturally revolt. The patient is told that he *must* rest so many hours a day; he *must* have his temperature taken so many times a day; he *must* take only so much exercise, if any; he *must* awake and retire at a certain hour; he *must* do this and *must* not do that. All these mandates that constitute the decalogue of tuberculous regimen cannot help but grate upon the already vitiated nervous system of the patient.

But in our zeal to help the vital organs regain their strength we are unmindful of this additional levy placed upon the nervous system.

Clearly we need a remedy for this—we need something that will bridge the gap—that in itself will generate the necessary nerve force. *Climate does this!*

The change of climate itself is a glimmer of hope exerting a salutary effect upon the mind of the patient. It helps him, in great measure, to regain his poise. It means a fresh start—a rekindling of that combative spirit that should dominate each patient and that never must be allowed to droop. He is confronted with new faces, new scenes, new backgrounds for the commonplaces of everyday life. He is gratified to find many who, like himself, had come there looking to the high heavens for hope and health, and had found them. He acquires more energy, more buoyancy. His black despair gives way to roseate hope. As a result, he ceases to be so introspective—he is less likely to keep thinking about his own condition—and, instead, begins planning for the new life that will come with complete restoration to health. In fine, the patient is elated to find that Nature is, indeed, a helpful ally in his fight against the enemy that is threatening his very existence.

The mental effect—or, if you will, the psychotherapy—of climate unquestionably merits greater consideration than ordinarily is bestowed on it. This is instanced by the fact that often a patient's condition will show improvement directly after his arrival and obviously before the physiological effect will have had time to manifest itself. On the other hand, should a patient develop an antipathy to a certain prescribed climate, he will seldom make good progress there and will do better elsewhere—even if the physical elements seem less auspicious.

In prescribing a climate for a consumptive, the mental element, therefore, deserves serious deliberation. Worry, fretting, anxiety, or other depressing condition militates against improvement in health. Much of the success of the attending physician will depend on his grasp of the mental characteristics of the patient. This phase of treatment, certainly, is no less important than the regulation of rest, exercise, food, and general mode of life.

In the very nature of things, the first question confronting the medical advisor will be, Is the change of climate absolutely essential? In considering this phase of the matter, the physician will do well to remember that countless cases of tuberculosis have been "arrested" *without* any change of climate.

Having satisfied himself on this score, the medical advisor may then proceed with the following practical catechism based on extended clinical experience:

Assuming that the change is essential, will the probable results outweigh the sacrifices involved—the breaking of home ties, the loss of business, the countless inconveniences and the not inconsiderable expenditure? Again, what vital resources does the patient harbor in himself? Is he fitted for travel? Will competent medical guidance be available? Will the food and sanitary arrangements be thoroughly satisfactory? Will the proposed environment harmonize with his mental make-up? Some like a quiet place, others prefer an animated place. Some are irritated by necessary association with strangers, others prefer company. One may not be happy unless his wife is at his side, another may not know what peace of mind is unless she is away.

Often a case will present itself where it seems advisable for a patient to locate permanently in a different climate. Here we are confronted with the additional question, Will he be able to earn his livelihood there?

In short, a thorough knowledge of the patient's habits and characteristics, together with an intimate insight into his peculiarities, is essential; for, in the final analysis, we are treating not *consumption* but the *consumptive*.

But, perhaps, the most dominant point to remember in connection with prescribing a climate for a consumptive is that *there is no one best climate for all cases* and that some patients will fare well in any fairly good climate providing they adhere to a suitable mode of life.

With these salient thoughts in mind, little difficulty indeed will be experienced in determining upon the proper climatic selection.

A DEVICE FOR DRAWING SMALL AMOUNTS OF BLOOD.

By Havens Brewster Bayles, M.D.,

Brooklyn, N. Y.

I WISH to offer to the readers of the MEDICAL RECORD who have occasion to draw small quantities (6 c.c.-30 c.c.) of blood (Wassermann) the description of a small, compact outfit, an improvement on that furnished by the New York Health Department. It is the usual experience, when the blood is drawn either by the physician unaided or with the assistance of patient or nurse, that more or less of it is spilled on the patient, doctor or floor, after the needle enters the vein and before the receptacle is procured and placed in proper position.

As seen by the accompanying diagram, a rubber stopper is inserted in place of the ordinary cork. This stopper is fitted with a short, hollow

needle, protected by a flange which is inserted through a small opening in the stopper and which acts as a vent. Another opening is made at the outer margin of the stopper, opposite the vent, for the insertion of the needle furnished by the department, and is so placed to put it in line with the vein; the beveled point must face the operator when the needle is inserted.

The technique is simple: Remove the cork from tube, insert rubber stopper, push needle through the rubber stopper as indicated by mark on stopper

as shown in diagram. We thus have a needle fitted into a tube, the latter serving as a handle, and the outfit is used much the same as one would use an awl. After the desired quantity of blood is withdrawn the rubber stopper is removed and the original cork inserted. The outfit is then ready to return to the laboratory for examination.

The rubber stopper should be washed under a faucet, sterilized, and placed in alcohol, ready for future use.

125 Seventh Avenue, Corner Carroll Street.

Medicolegal Notes.

Having Possession of Opium.—Under the revenue act of 1914 requiring all persons who produce, import, manufacture, compound, deal in, dispense, sell, distribute, or give away opium to register and pay an annual tax an indictment charged the defendant with conspiring with one Martin to have a dram of opium in the possession and under the control of Martin; and as the overt act charged that the defendant issued to Martin a prescription therefor, in bad faith, knowing it was not given for medical purposes, but for supplying one addicted to the use of opium. It was held that the indictment was insufficient. The unlawful thing charged consisted in having the drug in the possession and under the control of Martin, but the word "person" in the statute refers only to those required to register and pay the tax, and it was not alleged that Martin had the drug in his possession for any of the purposes for which he would have to register and pay the tax.—United States vs. Jim Fuey Moy, 225 Fed. 1003.

Burden of Showing Sale of Cocaine Not Unlawful on Defendant. — Section 808 of the Chicago Code of 1911 provides that "no druggist or other person shall sell or give away any morphine, cocaine, alpha or beta cocaine, chloral hydrate, or any salt or compound or derivative of any of these substances, or any substance, preparation, or compound containing any of these substances, or any of their salts or compounds or derivatives except upon the written prescription of a duly registered physician. It is held that the burden of proving in proceedings under the act that the sale was within the exception of the statute (because made on a physicians's prescription) is upon the defendant.—City of Chicago vs. Montgomery, 191 Ill. App. 558.

Keeping Opium for Personal Use—Burden of Proof—Registration and Taxation.—The federal district court, W. D. Tennessee, W. D., holds that under the Harrison Anti-Narcotic Act, the mere keeping of a small quantity of opium for personal use does not constitute an offence within the meaning of the act. Where a narcotic is found in a person's possession, he is presumptively guilty of violating the act, and then the burden of proof is upon the defendant to show affirmatively that he is not one of the class mentioned in Section 1 as required to register, or, if so, that he had registered and paid the special tax.

In a prosecution under the act, the uncontradicted evidence showed that the defendant obtained the opium found in her possession from a Chinaman, and that she had it for her personal use and consumption, and that she never sold, gave away, or dealt in it in any form. This evidence was held to overcome the presumption of guilt arising from the possession of opium under Section 8 of the act, providing that possession or control of opium shall be presumptive evidence of a violation of the act.—United States vs. Wilson, 225 Fed. 82.

Harrison Anti-Narcotic Law—Elements of Offence.—Section 1 of the federal act, Dec. 17, 1914, provides that every person who produces, deals in, etc., opium or coca leaves, or any compound or preparation thereof, shall register with the collector of internal revenue and pay a special tax. Section 8 provides that it shall be unlawful for any person who has not registered and paid such tax to have in his possession any of such drugs, and that possession thereof shall be presumptive evidence of a violation of both Sections 1 and 8. The federal district court, D. Montana, holds that, as taxes can be imposed and statutory offences created only by direct, clear, and apt language, the act does not impose the duty of registration and the payment of taxes upon mere consumers of the drugs, and only makes unlawful possession of the drugs by persons required to register and pay the tax, who have not done so. Indictments under the act, for not having registered and paid the special tax, but not alleging that the defendants were in any of the classes thereby required to register and pay the tax, were held to be fatally defective in substance and too uncertain to be sustained.—United States vs. Woods, 224 Fed. 278.

Harrison Anti-Narcotic Law—Application to Physicians.—The federal district court, W. D. Tennessee, W. D., holds that the Harrison Anti-Narcotic Law does not limit the amount of drugs a physician may prescribe, and an indictment charging a physician with prescribing drugs in quantities more than was necessary for the immediate needs of his patient, and not in good faith, is subject to demurrer. There is no duty imposed upon a physician by the act other than to keep a record of all such drugs dispensed by him, and the name and address of the patient, except those to whom he may personally administer, and that he must preserve the records for a period of two years.—United States vs. Friedman, 224 Fed. 276.

Regulation of Sale of Opium — Validity of Federal Statute.—The federal district court, W. D. Washington, N. D., holds that Congress may prohibit the importation of opium and regulate its relation to interstate commerce, as is done by Act of Dec. 17, 1914, providing for registration with collectors of internal revenue of dealers in opium, imposing a tax on dealers, and making it unlawful for any person who has not registered and paid the tax to have in his possession any opium or derivative thereof, and providing that such possession shall be presumptive evidence of a violation of the act.—United States vs. Brown, 224 Fed. 135.

Expert Testimony Based on Evidence.—The authorities differ as to the wisdom of permitting experts to express their opinions based on the evidence in a case instead of submitting hypothetical questions to them, but in Maryland it is permissible. In a prosecution for abortion, where there were several medical witnesses in the case who had treated the deceased, there being no conflict between them, the admission in evidence of the opinion of an expert who heard all but one of such witnesses testify was held proper.—Damm vs. State, Maryland Court of Appeals, 97 Atl. 645.

MEDICAL RECORD.

LOANS TO PHYSICIANS.

ONE of the Sherlock Holmes stories tells of a young practitioner who wished to specialize in a rather obscure branch of medicine. He was fortunate enough to meet with a rich, eccentric old gentleman who set him up in practice as a speculation; so much of his income went to his backer, who realized in time an excellent return on his money, while the young practitioner was thus assisted over what are usually the darkest days of a professional career. A case of that sort is exceptional, perhaps unique. Most of us live somehow through the first years of practice, maintaining clean linen and an automobile on an income varying from $5 to $50 a month in cash, $200 on the books, and untold thousands in experience. Of course, there are those favorites of fortune whom we envied in college days, the rich man's son on the one hand who will step into an office furnished from top to bottom in the best style, and on the other hand the physician's son, whom I think we envied even more—that lucky individual who was able to start out under the sheltering wing of the wise G. P.—who found his practice ready-made and expanded to fill it. The moralists may rave as they will about the blessings of poverty and toil and the curse of unearned case; few of us who sat in our simply furnished offices reading Osler or worse and waiting for the ring at the bell which turned out to be the installment man, did not envy the colleagues whose first years were devoid of worries.

A medical education is coming more and more to represent a large outlay of money besides the time involved. As medical colleges have practically abolished the night school it means that for four, five, or six years the student must live without working and in addition pay tuition fees, which grow higher all the time, buy books, instruments, etc. It was formerly the case that an enterprising young man with a good constitution could work his way through medical college; it often kept him on the edge of a breakdown, but it was done. Now, if a student can obtain a job of some kind during his vacation and find chances here and there during his school year to pick up a few dollars he considers himself lucky. Such a student, however, finds himself upon graduation face to face with a serious problem. He may, and often does, go in a hospital for a year or two, but this is only postponing the problem for most hospitals pay nothing or very little, certainly not enough from which to save anything. He is confronted with the task of fitting out an office, buying a machine perhaps, and undertaking to pay living expenses for several years before his practice shall become large enough to support him. The practicing physician, too, must present a good appearance, somewhat as the minister must. His clothing must be neat and not too threadbare, his linen clean, his machine, even though a rented flivver, must be kept in good order, although he himself should never be seen working on it, and a doctor must always be well fed and not appear to do any other work than his professional duties. Some optimistic souls accept this problem gaily, furnish apartments on the installment plan, buy a car on the same principle, run up a tailor's bill, and put themselves in the hands of Providence. Sometimes their faith is justified, patients flock in, and a year or so later they begin buying bonds and mortgages. Too often, though, the first two years are full of such nightmares as dodging the collector, placating various creditors, and at the same time showing a smiling, unruffled front to patients.

Now for a solution. We are inclined to think that it may lie in the direction of loans to physicians on their notes. The question of unsecured loans has always been a vexed one. Salaried employees are often driven to the loan sharks in large cities on account of the impossibilities of securing loans from banks. In some places cooperative companies have been formed which specialize in such loans and these have, as a rule, been fairly successful, but they necessarily deal in small sums, $25 to $100, as a rule. It would seem that a company might be formed to make loans to young physicians which would combine the advantages of being good investments and filling a real need. Dealers in medical books, drugs, and instruments are always ready to sell to the young doctors on the deferred payment plan; tradesmen, as a rule, trust them gladly; but all this does not solve the problem. It merely means a number of small debts for the doctor which all demand payment at the same time, and if one of them is neglected for a few months it amounts up alarmingly.

The details of the scheme hinted at above would require elaboration, but the main idea would be as follows: The company should consist partly of doctors and partly of business men. Some members, if possible, should be both. When a physician applied for a loan strict investigation should be made into his antecedents, his school record, etc. The locality in which he wished to practice would also have a bearing on the question. Then the company could rent and furnish his office, provide him with a car, and allow him so much a month. A report should be furnished by him every six months of his actual expenses and income. The extent to which the former exceeded the latter should be made the basis for the allowance for the next six months. This procedure should be repeated every half year, and as soon as the income exceeded the expenses arrangements could be made for paying back the principal. Besides the intangible security of character, the physician's note might be endorsed by two other physicians, a chattel mortgage taken on his furni-

ture and automobile, and an endowment policy payable to the company for, say, four or five times the amount of the loan, be kept up by the physician. When the loan was repaid this policy could be assigned to the physician, who would then have a start on a savings account. This scheme is undoubtedly impractical, being devised by a physician, but at least something of the sort, differing possibly in some of its details, might be arranged for the doctor who hesitates to take the plunge into the doubtful waters of general practice.

PELLAGRA AND SENSITIZATION TO MAIZE AND SUGAR-CANE PRODUCTS.

PERHAPS the most popular and best established theory at the present time regarding the nature of pellagra is that it is a deficiency disease, one due not to a lack of food in itself, but rather to a lack of substances in the food which are essential to a good state of nutrition.

At the third triennial meeting of the National Association for the Study of Pellagra at Columbia, S. C., Oct. 21 and 22, 1915, Dr. Roy Blosser read a paper dealing with the phenomena of sensitization to maize and sugar-cane products, in which he advanced the new theory that pellagra was due to this sensitization occurring in certain individuals. His claims as to the pellagra producing properties of the non-refined or partially refined sugar products were based on (1) a careful study of the dietetic habits of more than two hundred pellagrins; (2) the results obtained in such cases by the exclusion of certain articles of food; and (3) the effect of the experimental administration of these products to dogs. Blosser's experiments have differed from other attempts to produce pellagra experimentally in that meat and other foods were given with the sugar-cane ration, thereby eliminating any question as to the results being due to a lack of vitamines or to an unbalanced or unnatural diet. The result of his experiments appeared to show that a sugar-cane ration brings out unmistakable symptoms of pellagra.

PLATES AND BONE GRAFTS IN FRACTURES.

IN the hands of the introducer, Sir Arbuthnot Lane, the steel plate has had much success in the operative treatment of simple fractures, and it may be said that when Lane's technique has been closely followed, others have had excellent results from this mode of treatment. However, since autogenous bone grafting has come more or less into vogue various strictures have been passed upon the use of the steel plates. Among the many objections brought against their employment are that they act as foreign bodies; that they have a destructive influence on bone formation which may prevent the fractured ends from uniting; that a rarefying osteitis, or osteoporosis, or necrosis usually develops around the metal screws or nails, causing them to loosen and drop out; that metal favors infection, absorption, and disintegration of the tissues, and that the plates do not answer the purpose for which they are employed because they bend or break.

In the *Practitioner,* March, 1916, Lane ably defends his manner of treating fractures and in the *Canada Lancet,* July, 1916, E. R. Secord speaks very highly of steel plates as compared with the autogenous bone graft in the operative treatment of simple fractures. He points out that the first grand objection to the use of the bone graft is the amount of manipulation necessary to obtain the graft, and to prepare a suitable bed for its reception. The next great objection to the graft arises from the difficulty of fixing it in place with any degree of security. Consequently, the time required for a bone grafting operation is considerable. While a reasonably expert operator can "plate" a broken femur in half an hour, it will take him probably two hours to put in a bone graft. Secord states that at the Brantford General Hospital during the past few years they have operated on a considerable number of fractures by both plate and bone graft methods. They have never had to remove a plate, and have never seen any irritation result from its presence. All their cases have been radiographed subsequently, and no evidence has been seen of rarefying osteitis, or of loose, bent, or broken plates. He concludes that the use of the Lane plate appears to be safe, simple, and expeditious, but that a most rigid technique must be followed both during and after the operation, and that the great majority of failures after its use are due to faulty methods at the time, or to a failure to understand what may be expected of an internal fixation in any form. That the bone graft can be made to perform the same function is granted, that its use has certain advantages is admitted, but it is held that the difficulty of application and retention more than counterbalances these advantages.

SEASICKNESS.

SEASICKNESS has existed as long undoubtedly as men have traveled by sea and during this time, despite the countless remedies suggested for the distressing condition, no cure has as yet been discovered. In the *Médical Press* of July 12, 1916, is a paper by John F. McMillan in which he explains the sensations of seasickness as follows: Vertigo is a reflex condition due to some divergence from the normal of the semicircular canals, whereby through the auditory nerve abnormal impulses are carried to the medulla, and thence to the heart by the pneumogastric through its cardiac branches; and so far as the derangement that is common to the good sailor when he is confined below amidst oil smells, galley odors, etc., constitutes that form of the malady associated with vertigo, the main system, that is to say, the sympathetic, is unaffected. But do the waves pass beyond, to the gastric branches of the vagus, then are the original abnormal impulses from the semicircular canals communicated through its gastric branches to the center of the sympathetic system, the solar plexus, and then a second impulse is carried back to the stomach and causes the latter organ to evacuate its contents; and, although the whole may constitute one reflex movement, it is possibly a double one, the second being complete when food, actually placed within the stomach, during the first reflex is rejected; and then occurs the never-to-be-forgotten feeling of a

blow in the stomach. The spinal cord has been said to be concerned in the reflex or reflexes, and there has been mention made of muscular incoordination; but it is an easily solved question that beyond the movement caused by the lurch of the vessel, there is no muscular affection other than the inactivity due to vertigo and the gastric distress.

McMillan recommends nitrite of amyl to be inhaled with caution as required as efficacious with regard to the syncope associated with vertigo while as regards the solar plexus he thinks that the most useful remedy is an effervescent mixture, such as a Seidlitz powder, with the addition of a couple of drops of dilute hydrocyanic and 15 minims of spirit of chloroform.

The Alleged Increase of Cancer.

With regard to the increase of cancer, the views of those who have studied the subject closely are somewhat curiously at variance. While, perhaps, nearly all authorities are agreed that cancer has increased, many stoutly deny that this increase has assumed the alarming proportions ascribed by some writers and statisticians. At any time statistics are to some extent confusing and unless collected with great care and uniformity are apt to mislead. Moreover, in those countries in which there is not a uniform system of collecting and collating statistics, such figures cannot be taken as accurate and must be regarded with a certain degree of suspicion. Again, there are many things which enter into the question of cancer statistics, which render dogmatic statements unwise and even foolish. There is no space to discuss all of these here, but it may be said that some of the widely advertised statements that cancer is largely on the increase must not be taken without reservation. A part of this increase is apparent and a part real. Recently, Mr. Frederick L. Hoffman has brought out a book[1] with the rather ambitious title of "the mortality from cancer throughout the world," in which he states that the actual frequency of malignant disease throughout the civilized world has been ascertained to be much more of a menace to the welfare of mankind than has been generally assumed to be the case, and that, in contrast to a marked decline in the general death rate, cancer remains one of the few diseases actually and persistently on the increase in practically all of the countries and large cities for which trustworthy data are obtainable. Hoffman has collected and set down a mass of statistics and evidence bearing upon his point of view, and the book is a monument to his untiring and painstaking energy. While his work is not conclusive, it at least serves to show that cancer is unduly prevalent and that steps should be taken everywhere to control its spread, that is so far as is possible.

Treatment of Fractured Jaws.

One of the features of the treatment of wounds in the present war has been the success of the treatment of jaw wounds. In the American hospital in Paris the results obtained by the cooperation of surgeons and dentists in rectifying the effects of wounds of the jaw have been remarkable. Some of these results were shown on the screen in this city by Bainbridge after his return from the seat of war. In the *British Journal of Surgery*, August, 1916, Major A. C. Valadier gives a few suggestions for the treatment of fractured jaws. He draws attention to the fact that wounds caused by bullet or shrapnel will generally be complicated; that is to say, a piece of metal may lodge in a most vital spot. The following points have then to be determined: (1) Whether or not it is right immediately to attempt the removal of the foreign body. (2) Whether the patient will stand the strain of an anesthetic. (3) Whether the region of the glottis may be so inflamed as to contraindicate the use of a general anesthetic. (4) Whether the patient's oral cavity is so lacerated that food cannot be introduced. Should he be surgically treated at once to overcome this condition; or should prosthetic interference for the reduction of his fractured jaw be applied before surgical interference? These questions can only be answered by the oral surgeon in charge. Valadier points out that it is absolutely necessary for the sucecss of the procedure that the oral surgeon should work in perfect unison with the surgeon who is doing the plastic part of the operation.

[1] The Mortality from Cancer Throughout the World, by Frederick L. Hoffman, LL.D., F.S.S., F.G.S.A. Newark: The Prudential Press, 1915.

News of the Week.

Epidemic of Poliomyelitis Near End.—The rapidly decreasing number of new cases of poliomyelitis in the city encourages the belief that the epidemic is nearly at an end. During the week ending September 23, only 160 new cases and 58 deaths were reported, as compared with 254 cases and 84 deaths during the previous week. The total number of cases in the city to September 23, was 8,885, and the deaths numbered 2,233. After consultation with the Health Commissioner and the President of the Board of Education, Mayor Mitchell decided to have the public schools of the city open on Sepember 25, having reached the decision that the opening of the schools would be, not only safe, but actually beneficial to the children. The Health Commissioner has stated that during the school months of last year there were reported 20,668 cases of measles, 5,797 cases of scarlet fever, and 13,725 cases of diphtheria, the number of cases of each increasing month by month from October to June. The conclusion was drawn that if too great attention were paid to the spread of disease the schools would never be opened. More than $40,000 dollars has already been sent in voluntary contributions to the Health Department as a fund for the aftercare of children who have suffered from poliomyelitis. Surgeon L. D. Frick of the United States Public Health Service, who has been inspecting interstate travel through New York, has been ordered to Boston to assist the Health Commissioner of Massachusetts in the fight against infantile paralysis in that State. The statement that no cases of poliomyelitis developed among the babies receiving pasteurized milk from the Straus milk stations has been questioned by the officials of the Health Department. According to the records of the Department, out of 200 children under two years of age admitted to the Willard Parker Hospital during the epidemic, six were reported to have been users of the Straus milk up to the time of their admission.

Medical Colleges Open.—The Medical Department of the University of Georgia, Augusta, opened on September 14, with twenty-six men in the first

year class, and a total registration of over fifty. Dr. William H. Doughty, Jr., dean of the College, made the opening address.

The University of Tennessee, College of Medicine, Memphis, opened its new term on September 21, having added to its faculty three new members, Dr. Frank Maltaner, in the department of bacteriology and public health; Dr. W. E. Evans, in the department of biology, and Dr. John A. McIntosh, Jr., in the department of pathology.

1915 a Healthy Year.—A preliminary report of the Director of the Bureau of the Census gives the death rate for 1915 as 13.5 per 1,000 of population in the registration area of the United States. This is the lowest rate on record. The rate is based on 909,155 deaths returned from 25 States, in one of which (North Carolina) only municipalities of 1,000 population and over in 1910 were included, the District of Columbia, and 41 cities in nonregistration States, the total population of this area in 1915 being estimated at 67,337,000, or 67.1 per cent. of the total estimated population of the United States. In 1914 the death rate per 1,000 of population was 13.6; and in 1913 it was 14.1; while for the five year periods from 1901 to 1905, and from 1906 to 1910, the average rates were 16.2 and 15.1 respectively. In New York State the death rate for 1915 was 14.6, as compared with 14.7 for 1914, and 15.0 for 1913. In New York City, with an estimated population on July 1, 1915, of 5,468,190, the death rate for the year was 13.9, as compared with 14.1 in 1914, 14.3 in 1913, and 19.0 as the average for the five year period from 1901 to 1905.

American Ambulance Service Extended.—The American Ambulance Field Service announced recently from Paris that there would shortly be formed a section of ambulances to serve with the French Army in the Balkans. The section will include thirty ambulances of the latest model, repair cars, a kitchen car, tents, and other accessories. As American volunteers have already served on the Yser, Aisne, and Somme, in Champagne, at Verdun, in Lorraine, and in the reconquered parts of Alsace, the establishment of a Salonica section extends the service to include almost all of the great campaigns of the French Army.

Gifts of Ambulances to Russia.—A motor ambulance, the gift of American and English women resident in Petrograd, was formally presented to the Russian Red Cross in that city on September 20, On September 24, fifteen motor ambulances of the field hospital presented by a group of Americans were formally accepted by the Empress of Russia. The presentation was made by Capt. Philip Lydig and Dr. Philip Newton. The new cars will be known as "The American Ambulance of Her Imperial Highness Grand Duchess Tatiana Nicolaieva." They will be sent to the front under command of Dr. Newton.

Austria to Admit Red Cross.—Austria-Hungary, it is announced from Washington, has decided to grant permission for the reestablishment of American Red Cross units in the dual monarchy. The units were withdrawn a few months ago because of lack of funds. It is probable that Germany will take similar action. The Allies have agreed to pass the units and their supplies through the blockade. It is estimated that each unit of four surgeons and eight nurses will cost $40,000 for six months, and the number sent will depend upon the amount of money available.

Memorial to Dr. Murphy.—Plans are under foot for the erection in Chicago of a memorial to the late Dr. John B. Murphy. It is probable that the memorial will take the form of an institution for surgical research, and it is hoped that at least half a million dollars can be raised for the purpose.

A Memorial Hospital.—In memory of his brother, Herbert Barber, Mr. James Barber of New York is erecting the main building of the Broad Street Hospital, at Broad and South streets, New York, and will furnish the equipment also. The institution will serve the district south of Fulton Street which has not heretofore had a general emergency hospital.

Gifts to Charities.—The Hospital for Deformities and Joint Diseases, New York, has received from Mr. Herbert Kaufman of Pittsburgh, through Dr. H. D. Frauenthal, a gift of one million dollars, to be used for the erection of a new building and as an endowment fund.

By the will of the late Theresa Scott of Philadelphia, the sum of $5,000 is bequeathed to St. Christopher's Hospital of that city for the endowment of a free bed.

In the distribution of the estate of the late Mr. Eugene I. Sauter of Philadelphia, awards are made as follows: St. Christopher's Hospital and Dispensary for Children, $2,500; Children's Seashore Home, Atlantic City, $2,500; Presbyterian Hospital, Philadelphia, $5,000; Rush Hospital for Consumptives, Philadelphia, $5,000.

The Flushing Hospital, New York, receives by the will of the late Mr. S. Vernon Mann of New York a sum sufficient for the endowment of a free bed.

Police and Fire Surgeons.—The New York Municipal Civil Service Commission will shortly hold an examination, applications for which must be filed before October 6, for the purpose of filling vacancies in the position of surgeon in the New York Police and Fire Departments, at a salary of $3,500 per annum for part time service. The duties of the twenty surgeons of the Police Department and of the ten surgeons of the Fire Department consist of examining all successful candidates for the services prior to their final acceptance, caring for all members during sickness and disability, and recommending for retirement those unfit for duty or beyond the age limit. In addition, the Fire Department surgeons maintain one active clinic where the members of the department receive treatment and medicine free of charge. Surgeons have the rank of battalion chief in the Fire Department and of Inspector in the Police Department and are eligible for retirement at half pay after twenty years of service. Applicants for the examination must be citizens of New York State and between the ages of twenty-six and forty years, and have had five years' experience. Further details may be obtained by application to the Municipal Civil Service Commission, New York.

Personals.—Dr. L. D. Bristol, for the past two years director of the State Public Health Laboratories at the University of North Dakota and professor of bacteriology and hygiene, has accepted the newly created Boston Dispensary Fellowship in Public Health in the Department of Preventive Medicine in the Medical School of Harvard University, Boston.

Mr. Barnett Cohen has resigned his position as laboratory assistant in the Health Department of Savannah, Ga., to become research assistant in public health in Yale University.

Medical Societies Combine Meeting.—The 152d semi-annual meeting of the Litchfield County Medical Association will be held in conjunction with the ninth semi-annual meeting of the Connecticut State Medical Society at the Charlotte Hungerford Hospital, Torrington, on Tuesday, October 3. Guests will be given an opportunity to inspect the new hospital between eleven and twelve o'clock, and addresses will be made by Dr. D. D. Reidy, president of the County association, and by Dr. Samuel M. Garlick, president of the State society. Dr. Joseph I. Linde of New Haven will give the results of observations on cases of infantile paralysis in New Haven, and Dr. Herbert K. Thoms of New Haven will speak on postpartum hemorrhage.

Medical Society of the State of Pennsylvania.—At the annual meeting of this society held in Scranton on September 19 and 20, the following officers were elected for the ensuing year: *President*, Dr. Samuel G. Dixon, Philadelphia; *1st Vice-President*, Dr. John B. Corser, Scranton; *2nd Vice-President*, Dr. Joseph W. Albright, Muncy; *3rd Vice-President*, Dr. George H. Boyer, Allentown; *4th Vice-President*, Dr. John O. Wagner, Beaver Springs; *Secretary*, Dr. Cyrus Lee Stevens, Athens; *Assistant Secretary*, Dr. Clarence P. Franklin, Philadelphia; *Treasurer*, Dr. George W. Wagoner, Johnstown. The next annual meeting will be held at Pittsburgh.

Southwestern Texas Medical Society.—The annual meeting was held at Laredo on September 13 and 14, the following officers being elected: *President*, Dr. Robert Lee Graham, Cotuila; *Vice-president*, Dr. Homer T. Wilson, San Antonio; *Secretary-Treasurer*, Dr. Louis J. Manhoff, Aransas Pass.

Obituary Notes.—Dr. Louis C. Ford of Milo, Me., a graduate of the Medical School of Maine, Portland, in 1877, and a member of the Maine Medical Association and the Piscataquis County Medical Society, died at his home on September 11.

Dr. James H. Shannon of Saco, Me., a graduate of the Jefferson Medical College of Philadelphia in 1884, and a member of the Maine Medical Association and the York County Medical Society, died suddenly at his some on September 13, aged 74 years. Dr. Shannon was a veteran of the Civil War.

Dr. William Henry Yeager died at Philadelphia on August 4 at the age of 44 years. He was graduated from Hahnemann Medical College of Philadelphia in the class of 1900, and was an associate professor of therapeutics and clinical medicine in his alma mater.

Dr. Leo Dinkelspiel of New Rochelle, N. Y., a graduate of Columbia University, College of Physicians and Surgeons, New York, in 1883, and a member of the American Medical Association and the New York State and County Medical Societies, died at his home on September 12.

Dr. Daniel Hennessy of Bangor, Me., a graduate of the Geneva Medical College, Geneva, N. Y., in 1866, and a member of the American Medical Association, the Maine Medical Association, and the Penobscot County Medical Society, died on September 10, aged 79 years.

Dr. Elisha Dyer Leffingwell of Oswego, N. Y., a graduate of the Bellevue Hospital Medical College, New York, in 1877, died at his home on September 12, aged 67 years.

Dr. Frances Merriam Myers of Mount Vernon, N. Y., a graduate of the Woman's Medical College of the New York Infirmary for Women and Children, New York, in 1892, and a member of the Medical Society of the State of New York, the Mount Vernon Medical Society and the Westchester County Medical Society, died at her home on September 14, aged 46 years.

Dr. Reuben Willis of Somerville, Mass., a graduate of the Medical School of Harvard University in 1867, and a member of the Massachusetts Medical Society and the Middlesex South District Medical Society, died at the Robert Brigham Hospital, Boston, on September 6, aged 74 years.

Dr. George C. Parker of Winthrop, Me., a graduate of Dartmouth Medical School, Hanover, N. H., in 1881, and a member of the Maine Medical Association and the Kennebec County Medical Society, died at his home on September 8, after a short illness, aged 65 years.

Dr. George H. Turner, Jr., until recently of Portland, Me., a graduate of the Medical School of Maine, Portland, in 1903, and a member of the American Medical Association, the Maine Medical Association, and the Cumberland County Medical Society, died suddenly from acute indigestion, on September 9, aged 38 years.

Dr. William P. Pariseau of Ware, Mass., a graduate of Laval University, Faculty of Medicine, Quebec, in 1904, died in Hampton Hospital, Springfield, on September 1, after a short illness, aged 37 years.

Dr. Philip P. Carlon of New York, a graduate of New York University Medical College in 1890, died in St. Mary's Home, West Hartford, Conn., on August 31, after a long illness, aged 54 years.

Dr. Martin Giesy of Aurora, Oregon, a graduate of Willamette University, Medical Department, Salem, in 1868, died recently at his home, aged 83 years.

Dr. John N. Preston of Pawtucket, R. I., a veteran of the Civil War, died at his home on September 8, after a long illness, aged 69 years.

Dr. Edward A. Schmitz of Wauwatosa, Wis., a graduate of the University of Illinois, College of Medicine, Chicago, in 1884, surgeon of Milwaukee County and city health commissioner of Wauwatosa, died at his home on August 30, aged 56 years.

Dr. Azaire M. J. Provost of Berlin, N. H., a graduate of the Dartmouth Medical School, Hanover, in 1898, and a member of the American Medical Association, the New Hampshire Medical Society, and the Coos County Medical Society, died at his home, from pneumonia, after a short illness, on September 10, aged 46 years.

Dr. William G. Brede of Minneapolis, Minn., a graduate of the University of Minnesota Medical School, Minneapolis, in 1906, and a member of the Minnesota State Medical Association and the Hennepin County Medical Society, died at his home from septic pneumonia, after a short illness, on September 5, aged 40 years.

Dr. Samuel Moore Reynolds of New York, a graduate of the Berkshire Medical College, Pittsfield, Mass., died suddenly at St. Luke's Hospital, New York, on September 7, aged 74 years.

Dr. Marcus Francis Brown of Billings, Mont., a graduate of the University of Illinois, College of Medicine, Chicago, in 1908, and a member of the Montana State Medical Association and the Yellowstone Valley Medical Society, died at his home, from acute dilatation of the heart, on August 28, aged 35 years.

Dr. Howard S. Justice of Hutchinson, Kan., a graduate of the College of Physicians and Surgeons, Keokuk, Iowa, in 1865, and a member of the Kansas Medical Society and the Reno County

Medical Society, died at his home, after a long illness, on August 24, aged 80 years.

Dr. Edward Louis Duer, formerly of Philadelphia, a graduate of the University of Pennsylvania, Department of Medicine, in 1860, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, the Montgomery County Medical Society, the Philadelphia Obstetrical Society, and the Philadelphia Pathological Society, died at his home in Odessa, Del., on September 6, aged 80 years.

Dr. Henri Iskowitz of New York City, a graduate of Columbia University, College of Physicians and Surgeons, New York, in 1905, died at his home on September 8, aged 31 years.

Dr. Enoch T. Jones of Hampton, Ark., a graduate of the Memphis Hospital Medical College, Memphis, in 1901, died recently at his home, aged 49 years.

Dr. Aaron J. King of Atlanta, Ga., a graduate of the Southern Medical College, Atlanta, died in a private hospital on September 8, aged 68 years.

Dr. L. L. Crump of West Point, Miss., died on September 5 from injuries received from a fall from his horse.

Dr. Albert James Mackay of Peacham, Vt., a graduate of the University of Vermont, College of Medicine, Burlington, in 1897, and a member of the American Medical Association, the Vermont State Medical Society, and the Caledonia County Medical Society, died on September 11, following an operation for appendicitis, aged 50 years.

Dr. William Henderson Mayfield of St. Louis, Mo., a graduate of Washington University Medical School, St. Louis, in 1883, died in the Mayfield Memorial Hospital on September 17, after a short illness, aged 64 years.

Dr. William L. Rogers of Atlanta, Ga., a graduate of the University of Georgia, Medical Department, Augusta, in 1879, died at his home on September 15, aged 63 years.

Dr. John W. Estes of Georgetown, Ky., a graduate of the Cincinnati College of Medicine and Surgery, Cincinnati, Ohio, in 1890, died suddenly on September 12, aged 68 years.

Dr. Adam W. Hubschmitt of New York, a graduate of Columbia University, College of Physicians and Surgeons, New York, in 1900, and a member of the Alumni Association of the New York Hospital, died on September 20.

Dr. Patrick Francis Hogan of Brooklyn, N. Y., a graduate of the University of Michigan Medical School, Ann Arbor, in 1872, died at his home on September 16, aged 65 years.

Dr. Josiah Herbert Keenan of Elizabeth, N. J., a graduate of New York University Medical College in 1895, died suddenly at his home on September 18.

Dr. Floyd Lee Van Wert of New Castle, Pa., 32 years old, was killed in an automobile accident on September 18. He was graduated from the medical department of the University of Pennsylvania in the class of 1910.

Dr. Thomas B. O'Reilly died at Philadelphia on September 18 at the age of 47 years. He was graduated from the Medico-Chirurgical of Philadelphia in the class of 1893, and then served a term as interne in the Philadelphia General Hospital.

Dr. Alexander Williams Biddle of Philadelphia died at Isleboro, Me., on September 19, at the age of 65 years. He was graduated from Jefferson Medical College in the class of 1879.

Correspondence.

NITROUS OXIDE-OXYGEN ANESTHESIA.

To the Editor of the Medical Record:

Sir:—In correction of Dr. Baldwin's statement in your issue of July 29, regarding deaths under nitrous oxide-oxygen anesthesia in this hospital, we beg to make the following references from the records of the hospital: During his short interne service in the hospital, Dr. McCormick never gave a gas anesthetic alone, although our anesthetizer attempted to teach him its administration and was always present throughout the entire anesthesia. No patient died in the hospital directly or indirectly as a result of nitrous oxide-oxygen anesthetic or under other anesthetic during his stay. During the past five years several thousand gas anesthetics have been administered in this hospital, 99 per cent. of which were given by a woman physician who has specialized in the administration of anesthetics for seven years. Instead of "seven or eight deaths" during nitrous oxide-oxygen anesthesia, as stated in Dr. Baldwin's article, we have never, until a few months ago, had a death that could be in any way, directly or indirectly, attributed thereto. About five months prior to this date, one death occurred during nitrous oxide-oxygen anesthesia in a patient who submitted to an operation as a last resort and was physically incapacitated from taking ether. The records of this hospital are open to Dr. Baldwin or to any interested physician or surgeon who cares to investigate any medical or surgical condition or make scientific inquiry in reference to our work.

W. L. Babcock, M.D.,
Superintendent, The Grace Hospital.

Detroit, Mich., Sept. 20, 1916.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

LOCAL GOVERNMENT BOARD—PROPOSED SCHEME AS TO VENEREAL DISEASES—DISTRIBUTION OF SALVARSAN—QUALIFICATION OF PRACTITIONERS DISTRIBUTING—MORTALITY OF MEDICAL OFFICERS—OBITUARY.

London, September 1, 1916.

The Local Government Board has had the City Corporation and the County and Borough Councils addressed in regard to venereal diseases. A scheme embodied in a circular has been approved by the profession who will cordially cooperate with the government department. It is suggested that it would be a great advantage if committees of local authorities invited the medical men in their several localities to nominate representatives to attend all meetings at which schemes may be discussed and to assist with their special knowledge of the needs of their particular areas. One of these representatives should in the usual way also represent the medical staffs of the hospitals and another the general practitioners in each administrative area. Mr. Long is anxious that each scheme shall meet the local needs in the fullest possible way and thinks the plan likely to secure the cooperation of the profession.

Questions have been raised as to the safeguards which ought to be taken in the distribution of salvarsan or its substitutes. The Local Board intends to supply those drugs for the purpose of intravenous administration to patients free to practitioners who produce satisfactory evidence of training or experience in their use. It is not thought desirable

to lay down hard and fast lines, but it is considered that as a general rule the drugs might properly be distributed by the medical officer of health or his agent, who should be required to satisfy himself before issuing a supply that the applicant is a registered practitioner who possesses one of these qualifications: (*a*) holds a certificate of having satisfactorily fulfilled the duties of clinical assistant in a hospital department recognized by the L.G.B. in connection with the scheme of the local authority, (*b*) holds a certificate of attendance at a course of instruction in the diagnosis and treatment of these diseases in their communicable stages, including intravenous medication, this to be in a recognized medical school or post-graduate college; (*c*) is or has been within the last five years a member of the permanent staff of a hospital of not less than fifty beds; (*d*) has had, in addition to the preceding adequate experience in intravenous medication.

The mortality of German medical officers in the present war has been heavy. Up to the middle of January the deaths are reported to have been 56. There were, in addition, 216 wounded, 40 made prisoners, and 94 are missing, while 29 have died of disease or wounds, 5 from accidents, and 2 are sick. These figures have been published as out of a total number of 12,000 serving with the army, but not including those in military hospitals, besides a further 10,000 in reserve hospitals, sanatoria, prisoners' camps, and ambulances. As Germany has about 32,000 medical men, this would leave only about 8,000 available for civil practice.

The death has occurred of Lieut.-Col. George M. J. Giles of the Indian and Canadian Medical Services. He took part in the South African war of 1878-9 and received the medal with clasps. When the present war broke out he was living at Kingston, Ontario, and joined the Canadian Army Medical Service. Returning to England he became medical officer to Burcote Hospital, but retired in March last on account of ill-health. He was author of "Climate and Health in Hot Countries" and one of the editors of the *Journal of Tropical Medicine*.

OUR LETTER FROM ALASKA.

(From Our Special Correspondent.)

UNUSUAL INTOXICATING BEVERAGES USED IN ALASKA.

ST. MICHAEL, ALASKA, Aug. 24, 1916.

IT is probably not known how long the human race has been addicted to alcoholism, but the first paper on the subject was written in 1789 by John Coakley Lettsom, one of the original founders of the Medical Society of London. With the advancement of science many new intoxicating beverages have come into use. Many other liquids containing from a fraction of 1 per cent. to 50 per cent. or more of alcohol are used as intoxicating beverages, although they are not put on the market for that purpose.

The Territory of Alaska is not "dry," but the sparsely settled country with limited and slow transportation has invited many persons who long for the physiological effects of alcohol and cannot obtain it in the usual beverage form, to attempt to manufacture or to use some other liquid which contains alcohol. It is not uncommon in some places in Alaska where there are no saloons to see a man go into a trading post or general merchandise store and say that he wants something to drink and ask, "What have you that contains the largest per cent?" "How much has this?" "How much has that?" meaning the percentage of alcohol and pointing to some medicine, perfume, toilet water, flavoring extracts, etc., on the shelf. There are many persons in Alaska, both white and native, who resort to various means of securing alcoholic intoxicants. The most common of these unusual alcoholic drinks in places which are in touch with civilization are the flavoring extracts. I mean by places that are in touch with civilization, a place that has a store or a trading post. In towns that are large enough to have a saloon, the saloons are patronized. It appears not to make any difference whether the extract be lemon, ginger, vanilla, pineapple, or what. It is sometimes drunk straight and at times mixed with cider, grape juice, milk, "sourdough," root-beer, or hot water. Sugar may or may not be added. Most of these extracts contain about 80 per cent. alcohol and their consumption in Alaska as a beverage has become so great that it is now a violation of the law to sell them to a native or to any one for drinking purposes. It would be interesting, indeed, to know just how much of these extracts is consumed in Alaska annually for drinking purposes, but it must be a large quantity, as every one seems to know of them and talk about them as intoxicating drinks. Through this port alone the amount of extracts shipped appears all out of proportion for their use for flavoring purposes considering the population.

In places that are not in touch with civilization, especially native villages, "sourdough" is the favorite intoxicating drink. This is sometimes called "hootch" or "hootchinoo." The latter term is thought to have originated in Kamchatka, across Bering Sea, in Russia, from whence the art of making sourdough probably spread to Alaska. The term "hootch" is a slang expression and is at times used to designate any intoxicating liquor, while hootchinoo is more properly distilled sourdough. Sourdough is made by mixing a very thin dough of flour and water, adding yeast, and setting aside to ferment. This fermentation is facilitated by placing the vessel in warm water or in a warm place. As the fermentation takes place, the liquid turns an amber color and large flakes of starch float to the top, later to settle to the bottom leaving a clear colored liquid on top. Rice and barley are sometimes used instead of flour, and it has been said that the addition of molasses to the fermenting mass makes a stronger preparation. The entire mass has a sour smell, hence the name sourdough. Alcohol is formed during this fermentation and after it has reached the required percentage, the liquid is strained. Some persons drink the liquid just as it is strained off, and this is the usual way. Sometimes the liquid is distilled, giving it a better smell and taste and making it clearer and more concentrated. As this method requires some apparatus, time, and experience, it is the uncommon form. This liquid appears to be much more intoxicating than beer and the laws of Alaska prohibit its manufacture. The writer has seen persons so intoxicated from its use as to threaten the lives of others and require confinement. A "sourdough fiend" told the writer a few days ago that the addition of a teaspoonful of wood ashes to a pint of sourdough very materially increased its intoxicating qualities.

Although it requires some apparatus to make hootchinoo—the distilled sourdough—it is remarkable what simple apparatus may be used for this distilling purpose. A common homemade still is made by taking two coal oil cans and connecting

them with a pipe. The pipe enters one and passes through the other. The sourdough is boiled in the former and condensed by ice in the latter, the hootchinoo dropping out of the end of the pipe as a colorless alcoholic liquid. In the absence of a pipe, gun barrels have been used for this purpose, and it is believed that there are many houses in Alaska which have some such apparatus in them.

When the materials can be obtained the following is a favorite method of manufacturing hootch: about a pint of sourdough is mixed with about a gallon of cider or grape juice and the mixture is left open for several days in a warm place. This mixture become quite intoxicating. As these liquids are not consumed for their taste but for their effects only, a great deal of trouble results in Alaska from their use. There are special agents for the suppression of intoxicating liquors among the natives of Alaska and probably no other alcoholic drink gives these agents as much trouble as sourdough. It may be interesting to note that a white man who spends more than one year in Alaska is called a "sourdough." The "sourdoughs" say this is due to the fact that the white men make sourdough (yeast) hot cakes, while the natives say it is because of the early adaptation of the white man's taste to "the native drink."

2. The Present Status of Alveolar Osteomyelitis. Leon S. Medalia.
3. The Use of Emetine. Alfred C. Reed.
4. Peripheral Neuritis Following Emetin Treatment of Amebic Dysentery. A. R. Kilgore.
5. Dystonia Musculorum Deformans. Isadore H. Coriat.

3. The Use of Emetine.—Alfred C. Reed presents the salient features of the history, pharmacology, toxicology, and use of emetine, and, in summarizing, states that in so far as emetine has a beneficial action in tuberculosis, it would seem to be due to its expectorant properties, and if so, other preparations are preferable. In so far as emetine has a beneficial action in hemorrhage, it would seem to be due to the indirect result of decreasing the blood pressure, and if so, other drugs would be more effective, in that they would produce a similar result more safely and without the specific action of emetine on coagulation. Levy and Rountree make the suggestion which can hardly be taken seriously from the clinical point of view, that emetine enemata would serve a useful purpose in the treatment of constipation. Such enemata have an undoubted value when properly used for the sake of their amebicidal action, but their use as here suggested does not seem well advised. Emetine will hardly replace Leonard Rogers' hypertonic infusion in Asiatic cholera, and few of its other applications will bear the test of careful experimentation. Whether emetine alone will cure pyorrhea is an open question. It will, without doubt, cure the amebic infection, and to this end its use hypodermically and locally is indicated. But it cannot be said that emetine is a specific for pyorrhea, or that pyorrhea cannot be cured without it. This statement is also applicable to certain bony and oral abscesses and infections other than pyorrhea. Emetine has proved serviceable in the treatment of certain other diseases caused by animal parasites, especially protozoans, but its main action is on the ameba, for which it is a specific remedy, provided the specific agent is not walled off in an abscess.

4. Peripheral Neuritis Following Emetine Treatment of Amebic Dysentery.—A. R. Kilgore reviews the main by-effects of emetine hydrochloride and reports a number of cases which serve to call attention to the frequency of the occurrence of peripheral neuritis after emetine. He finds that peripheral neuritis after emetine is not uncommon. The symptoms most commonly met with in post-emetine neuritis are general muscular pain and weakness, usually most pronounced in the legs, sometimes going on to paresis. One case is here reported of hyperesthesia of the soles of the feet without other symptoms. The neuritic symptoms often develop after the emetine injections have been stopped, and may grow progressively worse for some time with no more administration of the drug. The total amount of emetine necessary to produce neuritis varies greatly. The total amounts received by the cases of Levy and Roundtree and of the writer varied from 21.3 grains in an adult to 4 in a child of four years. On the other hand many patients received larger amounts and had no symptoms. The prognosis is good. The symptoms clear up gradually, usually over several weeks, leaving no traces apparent. Experiments now in progress suggest that peripheral neuritis may be produced by emetine in healthy dogs.

5. Dystonia Musculorum Deformans—Oppenheim's New Disease of Children and Young Adults.—Isadore H. Coriat reports three cases of a disease described by Oppenheim in 1911 as occurring in young people of Russian or Galician Jewish parentage, which he termed dysbasia lordotica progressiva or dystonia musculorum deformans. He attempted to separate the disorder from the tics, athetoses, and the various muscular spasmodic states occurring in hysteria. At first the racial predilection of the condition suggested a comparison with amaurotic family idiocy, but more recent studies have shown that while the disease is preeminent among young Hebrews, yet it is not absolutely limited to them. The first two cases reported strongly resembled an hysterical dysbasia, but without any corresponding sensory disturbances; in the third case there was evidence of some organic affection of the nervous system, as shown by spasticity, gait, bulbar symptoms, and the variations in muscular tonicity, yet lacking the usual pathological reflexes of the spastic groups of diseases. In one case the condition followed a slight trauma, in another it appeared after a tonsillectomy, while in the third, it was engrafted on a highly neurotic and probably latent hysterical individual. The prominent features in all the cases were the peculiar gait, the changes in the muscular tonicity, and the rapid onset of the disease without any pathological reflexes or changes in sensation. All reported cases show that it begins in an extremity. The disorder presents certain difficulties in diagnosis because of its obscure relationship to hysteria, on the one hand, and to organic diseases of the nervous system on the other. For this reason it is difficult to place the condition in any definite nosological entity.

1. **Epilepsy.**—Charles A. L. Reed reviews the evidence that he has brought forward to show that there is present in the blood of epileptics an organism not present in other individuals, that this organism is forced from the alimentary canal into the circulation by the anatomical disturbance of mechanical stasis, and that this sequela has been shown to be present in 100 per cent. of his cases of epilepsy. If these things are true the immediately consecutive stages of the pathological process intervening between absorption and convulsion become matters of interest. The toxemia of epilepsy is shown by the constant tendency to a subnormal temperature and by the elimination of various toxic products in the urine. Chronic acidosis, profound, always obstinate, often almost irreversible, exists in 100 per cent. of epileptics. It is but natural that acidosis of this character should be followed by edema especially marked in organs and structures upon which the primary infection exercises a selective action. It would seem that the *Bacillus epilepticus* exercises its terminal effects by producing a terminal deinsulating edema of the conduction paths of the brain, as in purely convulsive disturbances; or of both the conduction paths and the cortex, as with convulsions with psychic explosions. It seems therefore that if diagnostic studies of epilepsy are really to be made, it will be necessary to broaden the usual methods of investigation. Actual examination of the cases must embrace, first, the blood with reference to the presence or absence of *B. epilepticus*, and for the further purpose of determining the blood values; next, the careful *x*-ray examination of the abdominal viscera with reference to determining more particularly the position of the stomach and intestines and the transit of ingesta through them; third, the repeated analysis of the urine and saliva with reference more particularly to the existence and degree of acidosis. In the light of the evidence in the hands of the profession it may now be said that any examination of epileptics that stops short of these features necessarily stops short of diagnostic accuracy.

2. **Reed's Bacillus of Epilepsy.**—A. J. Hinkelmann states that, on the basis of experiments made during the summer of 1915, and before he had any knowledge of the pathology of the organism, he found it a frequent inhabitant of the intestinal tract. The universal presence of the organism in the intestinal flora is no argument against its probable pathology, but simply adds to the importance of the gateway through which it enters the blood stream, in considering the treatment. Observations show that the organism is highly hemolytic and to this fact may be due a part of the pathological conditions present in epileptics. Cultures made on blood agar plates will show a hemolytic spot long before the colony itself becomes visible. In the opinion of the author the fact that the organism does enter the circulation and there multiplies into great numbers, and is so generally found in the blood of epileptics, makes the conclusions of Reed as to its specific nature at least very plausible.

3. **The Pathogenesis and Treatment of Epilepsy.**—Henry A. Cotton, E. P. Corson-White, and W. W. Stevenson present this preliminary report from the Laboratory of the New Jersey State Hospital from which they conclude that: 1. At least one type of epilepsy is probably a disease process dependent upon absorption of toxic or poisonous products from the intestinal canal. 2. This stasis may be produced by an overaction of the suprarenal gland. 3. Hyperactivity of the adrenal gland may be caused by, a, dysfunction of pituitary, b, dysfunction of pancreas, c, irritation of duodenum, d, severe fright or emotional disturbance. 4. Treatment by administration of pancreatin should be employed in preference to surgical procedures. 5. Surgical procedures should be employed in long standing cases where other treatment fails.

4. **Toxic Manifestations of Epilepsy and Their Rational Treatment.**—Ralph H. Spangler records his clinical observations and the results of various blood tests made in over 300 cases of epilepsy. He concludes that in many of the so-called idiopathic cases of epilepsy, the attacks are caused by a toxin carried in the blood. The accumulation of this toxin in an epileptic will cause an attack, associated with general leucocytosis, but not an eosinophilia. The blood of an epileptic injected into an animal causes a general leucocytosis with a marked eosinophilia. A patient afflicted with epilepsy in most instances does not produce, or has lost the power to produce, an eosinophilia; the toxin is not antagonized and an attack occurs, that is, in a patient afflicted with epilepsy the toxin is negatively chemotaxic for eosinophile cells. The clotting time of the blood is shortened before an epileptic seizure. The range of clotting time of the blood in 85 per cent. of the cases in a series of 100 patients was shorter during interparoxysmal period (1.5 to 4.5 minutes) than it is in normal subjects (three to eight minutes as given by most investigators). The alkalinity of the blood is lower in cases of epilepsy than in control, non-epileptic subjects, on the same diet. The hypodermic injection of crotalin in properly regulated doses has produced moderate degrees of eosinophilia, has lengthened the clotting time, and increased the alkalinity of the blood in certain epileptic patients, thus greatly modifying the character of the seizures and in some cases holding the attack in abeyance indefinitely.

10. **An Invariable Blood Stain.**—B. G. R. Williams recommends the following method of blood staining because the technique is simple, rapidly completed, gives results which are invariable and sufficient for diagnostic purposes, and it is practically impossible to overstain with it. The hematoxylin used is the Ehrlich formula: Mix:

Hematoxylin	2
Glacial acetic acid	10
Glycerin	100
Absolute alcohol	100
Distilled water	100
Potassium alum (an excess).	

The invariable stain is made by adding to this filtrate 0.1 gram of water soluble eosin. This stain is not self fixing; the author uses the alcohol flash method of fixation, though he says it is possible that other good methods may answer. The picture is that given by any hematoxylin and eosin methods. By this stain it is easy to diagnosticate the various anemias, leucemias, eosinophilias, etc. Differential counting is much more satisfactory than with Wright's because of the excellent nuclear staining.

1. **The Prevalence of Chronic Mouth Infections and Their Management.**—Frederick B. Moorehead has examined the histories of 718 cases, including 498 cases of chronic arthritis, 70 cases of chronic infections not joint lesions, and 150 private office cases referred for mouth examination because of some systemic disease, with the object of determining the incidence of chronic mouth infections. In the first group 89 per cent. had alveolar abscess; in the second group 74 per cent., and in the third group 69 per cent. The overwhelming majority of chronic abscesses were associated with previously treated root canals, a fact which serves to emphasize the importance of root canal technique. The essayist concludes that both in diagnosis and in determining the extent of tissue lost, the Roentgen ray is of paramount value. The involvement of the peridental membrane is the crux in deciding between conservative and radical treatment. Faulty root-canal technique. the careless use of arsenic as a devitalizing agent, and irritating drugs in the treatment of root canals are strong predisposing factors of chronic alveolar abscess. In carefully selected cases, conservative measures should be employed both in the treatment of chronic abscess and chronic suppurative pericementitis. Where root canals have been disinfected and filled, portions of roots resected, etc., the process of repair should be checked up by roentgenograms made at frequent intervals. Regardless of whatever form of treatment may be employed, the removal of infection is imperative in all cases, whether the patient at the time may be well or ill.

2. **The Principles Involved in Focal Infection as Related to Systemic Disease.**—Frank Billings discusses the principles of infection under the following three headings: 1. The pathogenic microorganisms and the conditions which modify their virulence and pathogenicity. 2. The host, or infected individual, and the conditions which modify his susceptibility to infection. 3. The nature and result of the reactions between the infectious agents and the tissues of the host. He concludes that the laws which govern the perpetuation of the pathogenic microorganisms involve a life of parasitism harmless to the host or of varying degrees of pathogenicity. Apparently any specific type of bacteria which causes focal infection may attain the biochemic qualities which permit them to live in the host as harmless parasites or as injurious agents possessed of a special or general pathogenicity of varying virulence. The varying pathogenic qualities, special and general, may be acquired apparently in the host or in the passage from host to host (man or animal), or may be brought about in culture mediums. Confined infection (focal) seems to be a site in which infectious agents may attain specific pathogenicity, chiefly in the nature of tissue tropism (elective tissue affinity). This special quality is not recognized necessarily by cultural characteristics. The power to hemolyze or to produce green color in agar blood plates by some members of the streptococcus group does not necessarily indicate that specific pathogenicity or degree of virulence. The special or general pathogenicity of the infectious agents of focal infection, and the susceptibility of the host, measured by many factors, such as age, environment, social condition, occupation, habits, domiciliary and occupational environment, climate, physical well-being, etc., may determine the severity, acute or chronic, the extent, local or general, and the site, election of tissue, of the systemic infection. The writer believes that these conclusions are sustained by clinical observations and bacteriological research.

4. **Methods and Results in Gastric Surgery.**—George W. Crile. (See MEDICAL RECORD, June 17, 1916, page 1111.)

5. **A Roentgenological Study of the Gastrointestinal Tract in Diabetes: A Report on Seventy-two Cases.**—James T. Case, in this series of 72 diabetics, found gallstones in six cases, or 8 per cent., and in eight more cases there were very suspicious shadows, some of which were proved to be gallstones at subsequent operation. Evidence of gallbladder region adhesions existed in 26 of these cases and there was a correspondingly large percentage of cases of transverse stomachs. The findings in relation to the motor function of the stomach agree very well with the clinical studies of various investigators. Duodenal stasis was a rare finding in this series of cases, being observed only once. An increase in the dimensions of the duodenum, either in length or caliber, was not observed. There was a striking relation between the severity of the disease and the degree of ileac stasis. Ileocecal valve incompetency is a common finding in diabetics, but in this series there seemed to be no relationship between the degree of ileocecal valve incompetency and the severity of the disease. Adhesions of the terminal ileum, stasis in the cecum, and evidences of appendical diseases, were somewhat more frequent in the severe cases than in the mild cases in this series. The average emptying time of the colon was delayed in about the same proportion of cases as one would expect from a perusal of the clinical histories. A majority of the patients showed a low grade of colonic stasis. Extreme colonic stasis was found in only two cases, and both of these showed carcinoma of the distal colon.

6. **Direct and Indirect Hay-Fever: Preliminary Report of the American Hay-Fever Prevention Association on the Etiology of Hay-Fever.**—W. Scheppegrell states that their investigations show that there are two forms of pollen causing hay-fever; the first, spiculated in form and low in protein, causing direct hay-fever; the second, unspiculated in form and high in protein, causing hay-fever by absorption of the protein (indirect hay-fever). In direct hay-fever, the severity of the attack and its duration depend on the number of pollen grains in the atmosphere, and the length of the pollen spicules. The rag-weeds form the type and principal cause of this form of hay-fever. In indirect hay-fever, the severity of the attack and its duration depend upon the amount of protein contained in the pollen and on the number in the atmosphere. The grass pollens have the highest percentage of protein and form the type and principal cause of this form of hay-fever. Pollens without spicules and with an inappreciable amount of protein are innocuous in hay-fever.

7. **Brachial Plexus Surgery.**—Arthur Ayer Law. (See MEDICAL RECORD, July 1, 1916, page 35.)

8. **The Interest of the Community in Cancer.**—Louis I. Dublin. (See MEDICAL RECORD, September 16, 1916, page 525.)

10. **Don'ts to Be Emphasized in the Management of Hypertensive Cardiovascular Disease.**—Henry Farnum Stoll formulates the following list of "dont's": 1. Don't tell the patient with moderate hypertension, few symptoms and whose kidneys are functioning well to stop eating meat, or go on a milk diet. 2. Don't tell him to give up his business immediately; try to readjust his life so that unnecessary cardiovascular strain is reduced to a minimum. 3. Don't tell him his kidneys are "all right," just because his urine exhibits neither albumin nor casts. 4. Don't miss the significance of nocturnal polyuria and a persistently low gravity. 5. Don't give nitroglycerin tablets to your patient the moment you discover that he has hypertension. Perhaps he requires a high pressure to get the blood through his small inelastic vessels. 6. Don't be satisfied with the systolic pressure—the diastolic is often of more significance. 7.

Don't attribute the insomnia, nervousness and headaches in the middle aged woman to "the change"—take her blood pressure and examine her eye grounds. 8. Don't make a diagnosis of neurasthenia till after a blood pressure estimation and a Wassermann test. It may save subsequent embarrassment and even be of advantage to the patient. 9. Don't think you are doing your whole duty to your pregnant patient when you have examined her urine. She may have hypertension but no albumin today and eclampsia next week. 10. Don't consider hypertension solely a condition of middle life; it is occasionally present in childhood. 11. Don't forget the old man's enlarged prostrate. It may be the cause of the nephritic syndrome. 12. Don't hesitate to give digitalis when symptoms of cardiac failure are evident. It will not raise the blood pressure. 13. Don't wait until the patient is water logged and the heart dilated before suspecting a failing myocardium. 14. Don't deny your sleepless, gasping patient, whose course is nearly run, the relief that only morphine will give. 15. Don't make a prognosis solely on the blood pressure or phenolsulphonephthalein test. Each tells but part of the story. 16. Don't overlook the fact that cardiovascular disease is to a certain degree a familial condition sometimes present in several generations; nor neglect to explain the importance of a yearly blood pressure estimation of all members of the family. 17. Don't exclude syphilis, especially a parental infection, as the cause of hypertension solely because the Wassermann is negative. Study the family history; examine the brothers and sisters, and your patient's children for signs of hereditary syphilis. 18. Don't fancy that the management of hypertension consists in watching a column of mercury or that success is measured in millimeters.

1. A Prehistoric War Wound. Lionel F. West, with Note by Arthur Keith.
2. On the Salt Pack Treatment of Infected Gunshot Wounds. J. E. H. Roberts and R. S. S. Statham.
3. A Plea for Ignoring "Laudable Pus" in the Treatment of Septic Wounds. M. Donaldson, E. Alment and A. J. Wright.
4. Secondary Infection of Joints in Acute Medical Ailments. G. H. Edington.
5. Death under Nitrous Oxide Oxygen and Spinal Anesthesia. William E. Robinson.
6. Treatment of Wounds by Nascent Ozone. John Jeffrey.
7. A Case of Abdominal or Bilocular Hydrocele. F. O. Lasbrey.

2. On the Salt Pack Treatment of Infected Gunshot Wounds.—J. E. H. Roberts and R. S. S. Statham state that the method of dressing wounds with a firm pack of gauze and sodium chloride tablets, devised by Col. H. M. W. Gray, combined with a primary free excision of the wound and lacerated and infected tissues, has in their hands given results which have effected revolutionary changes in their methods of treatment. During the last twelve months it has gradually supplanted other methods of treatment until now it is employed in the majority of cases. They have found that wounds dressed in this way became clean at least as speedily as those treated by other methods and that the general condition of the patients improved owing to the undisturbed sleep, increase of appetite, and absence of mental apprehension of frequent painful dressings. In all cases side tracks and pockets are opened up so that they can be packed to the bottom. Where a fracture exists, fragments, unless they are small and completely detached, are not removed. These proceedings are not really so heroic as they at first sight appear, since most of the muscle excised has been infected and that not infected has lost its striation and contains hemorrhagic areas for a considerable distance around a gunshot wound. Such muscle will not regain its function and will ultimately be replaced by fibrous tissue. With the exception of iodine for the skin no antiseptic is applied to the wound. The salt pack is applied in the following manner: A piece of plain gauze, six to eight layers thick, is lightly wrung out of 5 per cent. salt solution and carefully laid in the wound so that it is in contact with the whole of the surface. No spaces should be left, as they rapidly fill up with pus. A few 40-grain tablets of salt are placed in the deepest recesses of the wound. The interior of the gauze-lined wound is then firmly packed with a roll or long strip of gauze moistened in the same way. The strip is carried alternately from one end of the wound to the other and numerous tablets of salt are laid between the successive layers. When the pack becomes flush with the surface a few more layers are applied and over that a thick wool dressing. Really firm pressure is used in applying both the pack and the bandage. In an ordinary fairly severe wound the pack is left undisturbed for five or six days, when the wound is redressed, usually under an anesthetic. The indications that the wound is not doing well and the pack should be changed are a continuously rising pulse rate, increasing edema of the limb, sudden onset of severe pain, persistent rise of temperature, a change for the worse in the patient's general condition, and oozing of pus from under the edge of the dressing. The salt pack has given very good results with flush amputations and in excised joints. It seems to be of great value at times when it may be impossible to renew dressings for several days.

3. A Plea for Ignoring "Laudable Pus" in the Treatment of Septic Wounds.—M. Donaldson, E. Alment, and A. J. Wright claim that their experience has taught them that the presence of pus in a well-drained septic wound is no impediment to healing, whilst the disturbance necessary for its frequent removal retards the process of repair. They state that cases have been left considerably more than a week without change of dressing, and during that time the temperature and pulse remained normal and the patient's appetite rapidly improved. Charts are presented to show that the temperature and pulse, although possibly very alarming in the first few days after the operation of drainage, soon settle down without any dressing being changed. After nine months of trial they have adopted the salt pack in the majority of septic wounds, except those of the head, thorax, and some septic arms and legs which are opened up and put straight into a saline bath.

4. Secondary Infections of Joints in Acute Medical Ailments.—G. H. Edington reports three cases of joint infections occurring as a complication in medical ailments. In the first case pneumococcic abscess of the knee and buttock occurred as a complication rather than a sequela of bronchopneumonia; in the second case a streptococcic coxitis followed a pneumococcic empyema, in which it was probable that the chest condition was a mixed infection; in the third case suppuration in the knee joint occurred during alleged cerebrospinal fever. The writer says it is usual to explain the implication of the joint as a metastasis occurring in a part whose natural power of resistance has been lowered, and in support of this explanation trauma is usually invoked. In none of these cases was there any history of injury to the joint. It would seem that the story of precedent injury, frequently trifling, of which so much is made in the light of subsequent events, often rests on a slender foundation. Even if it is assumed that secondary implication of a joint points to severity of the primary infection—large dose or particularly virulent strain—the question is still to be answered as to the choice of location of secondary infection. The influence on the primary disease of the occurrence of

joint infection is discussed and the treatment of an infected joint outlined. The importance of keeping infected joints at rest in a proper position; of aspiration, if distension by effusion occurs, and more especially of strict antisepsis if operation is undertaken, are emphasized. Observation shows that in some minds the presence of pus seems to indicate that antiseptic precaution may be avoided. It should not be forgotten that to secure an aseptic result in a case of abscess is a proof of surgical skill greater than that required for the successful termination of a case of abdominal section.

5. **Death Under Nitrous Oxide-Oxygen and Spinal Anesthesia.**—William E. Robinson reports this case which is quite similar to one recently reported by W. J. McCardie in the *British Medical Journal* of July 22. The patient was a fat, unhealthy subject, very anemic and nervous, with a history of many attacks of bronchitis. The pulse was small, rapid, and thready, and the case unsuitable for a general anesthetic. The patient was operated on for a uterine fibroid. Ten minutes after the injection of 0.6 c.c. of stovaine (10 cg. stovaine in 1 c.c. of normal saline) the administration of gas and oxygen was begun. Fifteen minutes after the injection of the stovaine the patient vomited and became partly conscious. After vomiting was over, the gas and oxygen was restarted and the patient was apparently doing well. A few minutes later she again vomited, but this time did not regain her breath. Her color was perfectly good; her pupils dilated, and there was no obstruction by vomit in the larynx. All efforts at resuscitation failed. It seems to the writer that the stovaine was not directly responsible for this fatality, for the time limit when its toxicity gives cause for anxiety had passed. The shock of pulling up the uterus could not have been responsible for this occurrence. The anesthesia was perfect and all sensory nerves must have been blocked. This left, therefore, the nitrous oxide gas as more directly the cause of death. It seems probable that, owing to the anemic condition of the patient, the oxygen was not able to enter into her tissues to any extent and the nitrous oxide gas therefore acted on her heart muscle, causing it to fail at the critical moment, when, owing to the act of vomiting, there was again increased intrathoracic pressure and so a dilated right side. The practical suggestion to be drawn from this experience is that one should be guarded in the choice of gas and oxygen added to a spinal anesthetic in the presence of marked anemia.

Primary Operations on the Skull.—There has been a most promising union between the Societies of Surgery and Neurology under one president, Godari. To facilitate a debate various questions were asked, the first being in regard to primary intervention in cranial wounds. The questions were as follows: Should one always operate? What are the types of operation permissible? In simple fissure of the external table, ought one to examine the state of the inner table? Is the flap operation preferable to crucial incision? What are the indications, technic and results of primary extraction of intracerebral projectiles? These questions were answered by different members, one of whom, Rouvillois, may be quoted because of his categorical answers. He states in regard to operation that an exploration procedure should always be made as soon as possible, preceded if possible with an *x*-ray. How we should operate and how far should we go in this direction depends on the degree of injury. If the dura is not involved the trephine should always be used in theory; but as an opening has already been made in the skull, it is sufficient as a rule to trim its edges until it conforms to a trephine opening. If the dura and brain substance are involved the flap operation seems to give better remote results, as compared with crucial incision, but there is much to be said in favor of the latter which gives better visual control of the brain, and better conformation between the wound of the skull and that of the scalp. We have to think of immediate as well as remote results, and each operation doubtless has a separate field. In regard to inspection of the inner table in connection with simple external fissure this should be done always. In regard to projectile extraction, the presence of a bullet, etc., within the cerebral tissue is always a great menace, and hence immediate extraction should be made irrespective of depth. Secondary extraction is indicated in two conditions (1) when there is full infection, usually in the midst of a cerebral abscess, and (2) when the ball lies in a scar or is simply encapsulated in the brain.

Signs of Apex Pleurisy.—Sergent considers this subject with especial reference to pulmonary tuberculosis and supra clavicular adenitis. All schematic categories are inconvenient and dangerous and each observer should report his own finds without making them conform to classifications intended to bestow on the victim a particular status upon which treatment is to be based. The clinician has or should have a thorough technique and knowledge of semeiology, and therefore should rank as a phthisiologist. Now the same symptoms may belong to quite different disease types. We have but one certain test of tuberculosis—the presence of bacilli in the sputum. We do not refer here to latent tubercle, which is all but universal, but to the active manifestations. Our knowledge of phthisiology is in the midst of a revolution, and much false teaching is being relegated to the scrap heap. The great question of the day is "to what extent may a patient without bacilli in the sputum suffer from latent tuberculosis?" All who make many autopsies are familiar with apical adhesions of the pleura. The degree of adhesion may vary within wide limits. The author does not refer alone to pleurisy which is secondary to some lesion of the parenchyma of the lung, but to cases in which the pleural lesions predominate, even to the extent of complete symphysis. There are a number of individuals not actively tuberculous who suffer from apical lesions, as shown by the stethoscope and *x*-ray, all other regions of the lungs being intact save perhaps for old calcified lymphnodes at the hilus. Let us examine the symptoms of these patients. There are certain pains—between the shoulders, in the inner aspects of the supra—and intraspinous fossae, supra—and infroclavicular fossae—which show not the slightest resemblance to neuralgia or myalgia, but represent pleurodynia. This is not constantly present and is aggravated by deep inspiration and coughing. It is absent in complete symphysis and is perhaps due to the cicatrization which produces adhesion. Symptoms are very numerous. There are various degrees of flatness on percussion; absence of fremitus, muscular atrophy in the subclavicular and subspinous regions. The auscultatory signs are very difficult to interpret and are responsible for many incorrect diagnoses. This also holds good for radiography, especially when the operator is not a skilled interpreter. With a sufficient autopsy experience and knowledge of pathologic anatomy, it should be possible to interpret correctly the finds of the stethoscope and *x*-rays. Two objective

signs possess considerable value, to wit, pupillary inequality associated with paralysis of the sympathetic of the affected side and supraclavicular adenitis, the latter the subject of many researches. The inflamed gland is elongated in shape, lies just behind and parallel with the clavicle and opposite the border of the sternomastoid muscle. The size and consistency, also the number of glands involved, may show great variation. This affection has nothing in common with ordinary cervical adenopathy. During the past 2 years the author has made a routine research for this symptom. Very often it means the existence of a pleurisy, less often of a pulmonary lesion. The gland often felt is the end of a chain which leads to the inflamed pleura. If the pleuritic process is acute the gland should be large and soft; if chronic, small and firm. Pleurisy of the apex is not a new disease, but one which has been forgotten. When well developed it has usually passed for a tuberculous lesion, and no less when only imperfectly developed. When adhesions alone remain it is called a stigma of old tuberculosis. But it is often a benign lesion, which diagnostic ignorance has termed an active focus. Hence the diagnostic significance of the supraclavicular lymphnode which, according to the case, may show the absence of an active pleurisy. In any case, however, such a subject is never tuberculous in the sense that one is who suffers from anemia, loss of weight, weakness, low blood-pressure, etc., etc.

Gazette Hebdomadaire des Sciences Médicales.

August 27, 1916.

Simulation.—Blum begins a study of this subject and the qualifications which the military medical expert must possess to reveal it. A circular to this effect was sent out in 1915 by the Undersecretary of State for the Sanitary Service. The medical men were warned as to weakness, negligence, indecision, laxness and incapacity. In private life the physician is governed by his conscience. In military life he is governed by his duty to the State. In private life probity in regard to the best interests of his clientele comes first, but in military life he is responsible to his superiors. The civil practitioner, placed at the bedside, gives a diagnosis warranted by the symptoms subject to revocation. The military practitioner has to think always of simulation. He may pronounce it simulation or leave the question open. He also must look out for the aberrant types of disease, while in civil practice he must search for normal types. The military man must be especially familiar with the influence on disease of trauma, which plays a minor role in civil practice. The civil practitioner reckons on an ordinary cure, while the military man thinks chiefly of functional recovery, which is often remote. For the expert tact will always beat great learning, and tact is unthinkable without quickness. The learned man overburdened with scientific data hesitates and wavers. The word "savant" has two meanings which fit the case, namely, "learned" and "clever." The clever man hits the nail on the head, goes straight to the mark, while the erudite doubts, fears, clips off branches, but lets the trunk grow.

Journal de Médecine de Paris.

August, 1916.

Dental Caries and Pulmonary Tuberculosis.—Rosenthal states that proper dental treatment is at times seen to do away with bacillary adenopathies (submaxillary) after failure of general management. This result has even followed the treatment of a single cavity, perhaps very small; or the extraction of an abandoned root, without any gingival reaction. The gland paquet is often very large. Mere toilet of the buccal cavity has also caused amelioration in these glandular cases. Sometimes the adenopathy has suggested syphilis, especially syphilitic scrofula so-called, which is believed to represent mixed infection. But while these glands do not yield in any plan of syphilitic treatment they have been seen to disappear spontaneously after treatment of the teeth. In school children it is almost a law that cervical and tracheobronchial adenopathy occur in children who have already caries (about 15 per cent.). Of the others it may be said "No caries, no adenopathy." It is a long known law in medicine that candidates for tuberculosis have not sufficient lime retention—that they are demineralized as to calcium—a condition which naturally favors dental caries. A tuberculous lung may be shown to have lost (or never to have had) one-third of its normal mineral content. The resistance of the teeth to caries is a good measure of the general resistance of the body to disease. "Recalcification" has long been one of the leading remedies for tuberculosis. Otherwise stated dental caries is a testament of the presence of tuberculosis and pre-tuberculosis. We do not invalidate this statement if we add that dental caries also paves the way for infection. It may even do this indirectly by interference with proper mastication. Without the latter one cannot be in perfect health. Bad prosthesis may also interfere with digestion. The sixth year molar is known to be the first to become careous; this is because it has been infected from the fifth tooth of the first dentition. Carfous molars are premolars of the first dentition, again are often the starting point of tuberculosis through resulting errors or nutrition. The modes by which carious teeth can contribute to tuberculosis constitute a surplus—they exist in such numbers that some modes are superfluous. For example, a simple lymphangitis from an infected gum may pave the way for tuberculous lymphnodes. The inflamed node takes on specific characters, becoming a bacillary granuloma, and this in turn may become secondarily infected with pyogenics. Thus mere scaling of the teeth often causes suppuration of tuberculous glands. Again dental caries may be the direct cause of pulmonary lesions by the lymphatic route. At present a remedy for this sequence of events must lie with the dentists.

Colloidal Silver and Puerperal Sepsis.—Willette sums up as follows: Colloidal therapy should be used intravenously in puerperal sepsis and may render great services. Aerobic infection (chiefly the streptococcus) is much more frequent and more amenable to colloidal therapy. Anaerobic and mixed infections require an oxidizing or mixed treatment. To attain success large dosage should be used—one should not fear possible ill consequences. Figures show that this treatment lowers the mortality, shortens the course of the disease and prevents a certain amount of complications. The rationale of the treatment is due chiefly to the entrance into the blood of matter in the colloidal state which behaves as an alterative, and brings about a crisis syndrome, with its temperature fall, leucocytosis, augmentation of urine.

Acids of Gastric Fermentation.—Pron has examined 194 specimens of washings from the diseased stomach in the fasting state and in the absence of food residues. In 167 cases or 86 per cent. he obtained evidence of acids of fermentation, divided up as follows: In ninety-three cases the lactic acid was found by Uffelmann's method, while in the balance the sole acids present were volatile. In order that these finds be pathological there must have been present before lavage a splashing stomach which at the same time contained no food residues, *i.e.* a strictly fasting stomach. When found after a trial breakfast the presence of fermentation acids has no necessary pathological significance.—*Comptes rendus de la Société de Biologie.*

Book Reviews.

NERVOUS CHILDREN. Prevention and Management. By BEVERLEY R. TUCKER, M.D., Professor of Neurology and Psychiatry, Medical College of Virginia, Richmond, Va.; Consulting Physician of the Juvenile Court, Richmond, Va.; Physician of the Tucker Sanatorium, Richmond, Va.; Neurologist to the City Hospital, Richmond, Va.; Consulting Neurologist to the State Epileptic Colony, Lynchburg, Va.; Neurologist to the Johnston-Willis Sanatorium, Richmond, Va.; Editor of the *Old Dominion Journal of Medicine and Surgery*, etc. Price, $1.25. Boston: Richard G. Badger; Toronto: The Copp Clark Co., Ltd. 1916.

THE average mother of to-day seeks eagerly for knowledge as to the best care of her child, and the need for books on all subjects of children is gradually being filled. Dr. Tucker's book on nervous children is an excellent addition to the group. The mother who seeks methods of controlling and teaching her child must read elsewhere, but for an understanding of the needs of the child and a suggestion of possible abnormalities she may well peruse Dr. Tucker's book carefully. The book is a good introduction to further reading, for it gives a simple presentation of embryological development and short explanations of elementary physiology and psychology.

The chapter on heredity and environment is excellent, and might well stimulate to further reading and study. The chapters on habit, and eugenics and sexual hygiene are also worthy of note. Enough is said at various points to waken a mother to the importance of the activity of the glands of internal secretion, and thus win her cooperation with the physician if treatment is necessary. Increased knowledge on the part of a parent is always helpful to the best medical work, and the understanding by parents that certain examinations are necessary will make such examinations more universal and thus be a great help to the sick child.

ELEMENTARY BACTERIOLOGY AND PROTOZOÖLOGY FOR THE USE OF NURSES. By HERBERT FOX, M.D., Director of the William Pepper Laboratory of Clinical Medicine in the University of Pennsylvania; Pathologist to the Zoölogical Society of Philadelphia, etc. Second edition, revised and enlarged. Illustrated with 68 engravings and five colored plates. Price, $1.75. Philadelphia and New York: Lea and Febiger, 1916.

THIS book is well adapted to the use of nurses and of such members of the laity as are desirous of obtaining a general idea of the nature of microörganisms and their relation to disease. The author has performed his work well, and has avoided the common error of trying to tell too much. The new edition contains more detailed information on general disinfection, the transmission of infection, especially in regard to those diseases spread by insects, and the peculiar phenomena of hypersusceptibility. The volume is a valuable addition to a useful series.

TREATISE ON FRACTURES. By JOHN B. ROBERTS, A.M., M.D., F.A.C.S., Professor of Surgery in the Philadelphia Polyclinic and College for Graduates in Medicine; Sometime Chairman of Fracture Committee of American Surgical Association; Membre de la Société Internationale de Chirurgie; and JAMES A. KELLY, A.M., M.D., Attending Surgeon to St. Joseph's, St. Mary's and St. Timothy's Hospitals; Associate in Surgery in the Philadelphia Polyclinic and College for Graduates in Medicine. Octavo of 677 pages with 909 illustrations: radiograms, drawings and photographs. Price, $6. Philadelphia and London: J. B. Lippincott Company, 1916.

"THE object of this book is to supply student and medical practitioner with a clear, concise, and systematic presentation of the subject of fractures." This is the first sentence of the preface and we may say at the outset that the authors have accomplished their task; and this was essential if the book were to be a success, since there are already so many standard works on this subject. There are many good points about this book, not the least of which is that the time a fractured arm, elbow, etc., should be kept in splints is usually definitely stated in terms of days and weeks—a matter of much help to the practitioner who handles comparatively few such cases and is not in a position to call in a surgeon. Most books furnish explicit directions regarding diagnosis and the application of a proper retentive dressing but fail to state, except in the most general terms when, if ever, the splints are to be removed. So far as the diagnosis and non-operative treatment both of fractures in general and of special fractures are concerned, the material is presented most systematically and is admirably arranged for teaching purposes.

On the other hand, the chapter on the operative treatment of fractures seems surprisingly weak—the full possibilities of the autogenous bone graft in these cases apparently have not been grasped by the authors. The illustrations are generally good but often unnecessarily multiplied, particularly as regards radiograms of special fractures; and the addition of the words "right" or "left," "anterior" or "posterior view" to the legends under illustrations will often clarify matters. Figure 353 on page 315 is a conspicuous example of this need, for it requires considerable study of the figure to avoid the impression that the musculospinal nerve is depicted as running from without inward on the anterior surface of the humerus. Irrespective of these and other criticisms that might be made, the book deserves and should enjoy general approval, especially for classroom work.

NEW CONCEPTS IN DIAGNOSIS AND TREATMENT. PHYSICO-CLINICAL MEDICINE. The Practical Application of the Electronic Theory in the Interpretation and Treatment of Disease. With an Appendix on New Scientific Facts. By ALBERT ABRAMS, A.M., LL.D., M.D., F.R.M.S. San Francisco: Philopolis Press, 1916.

THE author presents here a series of methods for the diagnosis and treatment of disease, methods radically different from those now in use and based largely on certain electrical reactions which he claims to have discovered. Time and further research alone will determine the true value of his work. The results which he claims to have obtained are nothing short of marvelous but it is impossible to accept them merely on the statements presented. They call for demonstration and substantiation in the hands of many careful and scientific workers and it is probable that it will be long before such confirmation is received. The author is evidently an enthusiast. As is natural in a work dealing with a new subject one encounters many neologisms but the number seems greater than necessary.

THOSE ABOUT TRENCH. By EDWIN HERBERT LEWIS. New York: The MacMillan Company, 1916.

AFTER a good deal of unnecessarily technical talk the author gets started on his story which is really one of great interest. The principal character is a Serb who passes himself off as a Persian and is first met in a polyglot community living with Doctor Trench in Chicago. The interesting part of the story takes place in the near East and has much to do with the incidents immediately preceding the outbreak of the present war. Actions and conversations are described with what seems to be authority so that the average reader will see little that is improbable in the tale. There is much philosophy that is apparently set up to be knocked down, but the author, after having set it in place, often loses interest in it and neglects or forgets to knock it down again. In spite of the confusion of the picture which is presented the story is a fascinating one and will easily fill up a little spare time.

TEXT-BOOK OF ANATOMY AND PHYSIOLOGY FOR TRAINING SCHOOLS AND OTHER EDUCATIONAL INSTITUTIONS. By ELIZABETH R. BUNDY, M.D., Member of the Medical Staff of the Woman's Hospital of Philadelphia; Gynecologist, New Jersey Training School, Vineland; Formerly Adjunct Professor of Anatomy, and Demonstrator of Anatomy in the Woman's Medical College of Pennsylvania; Formerly Superintendent of Connecticut Training School for Nurses, New Haven, etc. Fourth Edition, revised and enlarged. With a glossary and 243 illustrations, 46 of which are printed in colors. Price, $1.75. Philadelphia: P. Blakiston's Son and Co.

PREVIOUS editions of this work have been noticed in the MEDICAL RECORD, and we are pleased to observe that some of the suggestions made on these occasions have been adopted by the author. The fact of the book reaching a fourth edition is evidence that it fills a want in our educational literature. Dr. Bundy's book takes an intermediate place between the elementary works and those which aim at teaching nurses and others all that is known (or even surmised) on the anatomy and physiology of the human body. In view of the prominence of sexual hygiene at the present time, the chapter bearing on that topic might be enlarged with advantage. We notice that the author still clings to the idea that the ear has four bones.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-first Annual Meeting, Held at Washington, D. C., May 9, 10, and 11, 1916.

THE PRESIDENT, DR. J. WESLEY BOVEE, WASHINGTON, D. C., IN THE CHAIR.

(*Concluded from page 570.*)

Variations in the Blood Supply of the Ovary and Their Possible Operative Importance.—Dr. JOHN A. SAMPSON of Albany, N. Y., stated that the study of the blood supply of the ovary was undertaken for its anatomical interest, and also for its bearing on conservative ovarian surgery when a tube was removed without removing the ovary of that side, or the uterus was removed leaving one or both ovaries. The intrinsic blood vessels of the ovary and resection of that organ were not considered. The material consisted of six fetal tubes and ovaries, and thirty adult ones in which the arteries had been injected with bismuth, and ten adult tubes and ovaries in which the veins had been injected. The specimens were studied by means of stereoscopic radiographs, and for the sake of comparison ink tracings were made of the blood vessels on prints, using the stereoscope as a guide in following the course of the individual vessels. The prints were then bleached, leaving the tracing. The terminal portion of the uterine artery presented variations in its branching and distribution of these branches. This artery directly or indirectly through its branches supplied a varying portion of the ovary in all, the entire tube in six, the greater portion of the tube in twenty-three, the round ligament and greater portion of the broad ligament in all but one. In twenty-four of the thirty specimens the uterine supplied the proximatl portion ovary divided into two main branches, a lateral tuboovarian or tubal branch, and a mesial ovarian, the latter anastomosing with the ovarian branch of the uterine. In six specimens the lateral tube branch was absent. The ovarian artery supplied a varying portion of the ovary in all, the distal portion of the tube in twenty-four and portions of the broad ligament in all, but the latter to a lesser degree than the uterine. The actual blood supply of the ovary was a divided one—uterine and ovarian. In twenty-six of the thirty specimens the uterine supplied the proximal portion of the ovary and the ovarian the distal. In four specimens (four of six in which the lateral ovarian branch to the tube was absent) the lateral tubal artery arose from the main tubal artery (uterine origin) and supplied the distal portion of the ovary, taking the place of the lateral tuboovarian branch from the ovarian artery. In these four specimens the distal portion of the ovary was supplied by the uterine, the middle by the ovarian, and the proximal by the uterine. The blood supply of the broad ligament being both uterine and ovarian, the usual blood supply of the tube being both uterine and ovarian, and as the arteries of the broad ligament communicate with each other and with those of the tube and round ligament, and as the tubal arteries communicate with each other, all these structures must be looked upon as containing a potential blood supply to the ovary. Thus the uterine and ovarian arteries communicate with each other not only through the well-known uteroovarian anastomosis, but also through the above-mentioned vessels. The actual venous outlet of the ovary was partly through the ovarian veins, partly through the uterine. Its potential venous outlet was evident in the various communications between the venous channels of the uteroovarian plexus, the free anastomosis of the veins of the broad ligament and tube, and the communication of the plexus with the epigastric vein of the round ligament. The removal of the tube always encroached upon the potential blood supply of the ovary, and when the distal pole of the ovary was supplied by the tubal artery (four of thirty specimens), the actual blood supply of that portion of the ovary might be cut off. These anatomical studies suggested that if it was necessary to remove a tube without removing the ovary, it should be done with the least possible disturbance of the broad ligament, and even then occasionally the blood supply of the distal pole of the ovary would be cut off; also in hysterectomy with conservation of the ovary, the accompanying tube should be saved, if possible.

The Clinical Course of Cancer in the Light of Cancer Research.—Dr. HARVEY R. GAYLORD, Director of the State Institute for the Study of Malignant Disease, Buffalo, said that cancer was not one disease, but a great group of diseases. The various types of sarcoma in chickens caused by filterable viruses had taught us that there were neoplasms with specific agents which determined the character of the tumor. Progress required that cancer of different organs must be treated as individual diseases and studied individually. The study of immunity to inoculated cancer threw new light upon the clinical course of the disease. Successful surgery, *x*-ray, and radium treatments were all dependent upon immunity. Early operation owed its success to the fact that immune reactions in spontaneous cancer were strongest in the early stages of the disease. The effect of chloroform and ether anesthesia and loss of blood, dependent upon surgical operation, was shown to exercise a destructive effect upon the immunity. The author pointed out the directions in which cancer research offered promise of better treatment.

Cancer of the Uterus and Its Treatment.—Dr. JOHN G. CLARK of Philadelphia classified cancer under three divisions as regards its treatment: (*a*) the radically operative; (*b*) the radical use of the cold cautery, and (*c*) the use of radium or mesothorium. Statistics as to surgical results were now upon an accurate basis and demonstrated a higher percentage of cures from the radical abdominal operation than achieved by the less radical vaginal and abdominal methods. In rebuttal there might be offered the much higher primary mortality and the greater number of disabling sequelæ from the former over the latter operation. The dangers of the radical operation were great even in the hands of the expert, and prohibitive when performed by the surgeon of limited experience. Many so-called radical operations were mere makeshifts, the patient being subjected to much greater hazards without any appreciable gain over simpler methods, by an attempt to execute an operation which failed lamentably short of an ideal standard. As yet the use of the cold cautery was in the proving ground and was a procedure which, to be successful, must be radical, and, therefore, was likely to be attended with a high primary mortality as well as serious sequelæ. It must, therefore, show a higher percentage of ultimate cures to make it a worthy competitor of the radical operation. In the author's experience of two years with radium, it had given encouraging promise, first, as a palliative remedy, and, secondly, as a tentatively curative one. It was in no sense a miraculous panacea, for a considerable number of cases were not helped, for the malignant process did not appear to be halted, but might actually be expedited. The sequelæ, however, following its judicious employment, were comparatively insignificant as compared with the foregoing methods, and, therefore, if the patient was not helped she was, at least, spared the added miseries of unfortunate accidents. Because the radium was not a dependable agent in all cases, and because as yet the type of cancer which would be helped could not be forecasted, surgical measures must still be invoked, but might be supplemented by radiozation. The dictum of the last few years, "In case of doubt, extirpate the uterus," was now modified, for in all such instances we now applied radium. Thus far in no instance had hysterectomy been performed when radium had acted beneficially, for it did not appear logical that an operation could accomplish anything further. As experience now pointed, it would appear that radioactive agents were to serve an excellent supplementary remedy to surgery, offering better results in the operative cases and a definite hope in the inoperable.

The Extended Operation for Carcinoma of the Uterus.—Dr. REUBEN PETERSON of Ann Arbor presented the following summary and conclusions: (1) Further experience with the radical abdominal operation for cancer of the uterus confirmed the belief that it was an exceedingly dangerous procedure and would always be attended by a high primary mortality. (2) Even if the percentage of operability of cases of cancer of the uterus markedly increased in this country and elsewhere, there would always be borderline cases attended by a high primary mortality. (3) This was true because it was not always possible, even with the greatest care in examination of the patient prior to operation, to estimate the extent of the disease. (4) Errors in judgment meant death from shock if the disease was too far advanced or failure to complete the radical re-

moval of the cancerous uterus. (5) However, in spite of a high primary mortality, it was the only procedure, with the possible exception of the extended vaginal operation, which held out any reasonable promise of a permanent cure. (6) Primary and end results of the radical operation for cancer of the uterus must be considered together in order to judge of the good accomplished in a given series of cases. (7) Unless the operations were radical, the end results would be poor, and if they were radical the primary mortality must be high. (8) If the end results were poor, the burden of proof was upon the radical abdominal operator to show why he did not choose a much safer palliative procedure. (9) Since 1912, experience with 14 ordinary panhysterectomies for cancer of the fundus showed worse primary and end results than in 11 cases previously reported where radical removal was performed. (10) This showing and the results following removal of fundus carcinoma by various methods in the Wertheim clinic, as reported by Weibel, led to the conclusion that, because carcinoma of the fundus was more easily cured than when the cervix was involved, we were not justified in thinking it could be treated any less radically than carcinoma of the cervix. (11) The primary mortality in 59 cases of cancer of the cervix and fundus treated by the radical abdominal operation was 23.4 per cent. (12) The extent of the involvement in cancer of the uterus could only be determined definitely after the abdomen had been opened. If the parametria were not too much involved and the condition of the patient's kidneys, heart, and blood vessels warrant a prolonged and depressing operation, it was justifiable to attempt the radical operation. (13) During the past four years 124 cases of cancer of the uterus had been seen in the university and private clinics. The disease was so far advanced in 36 cases that operation was refused or nothing was done. The cautery method was tried in 58 cases and proved valueless except as a palliative procedure. (14) In spite of attempts to educate the public regarding cancer, the cases of cancer of the uterus seen during the past four years were more advanced than had formerly been the case. (15) The end results in 51 patients operated upon five or more years ago were most gratifying. Combining fundus and cervix cases, 27 of the 51 patients were alive and well after five years, or 56.2 per cent. of all cases operated upon, while 69.2 per cent. of all those surviving the operations were alive after five years. (16) Of 40 cases of cancer of the cervix operated upon five years or more ago, 18 of those surviving the operations are alive and well to-day. Thus 47.3 per cent. of the total number remain cured after five years, while 62 per cent. of those surviving the operation remain cured. (17) These percentages were obtained by Wertheim's formula where patients dying of intercurrent disease, or those lost track of, were subtracted from the total number of operative cases or from the number surviving. (18) The length of time elapsed since the operations upon the 18 patients who were alive and well varied from five to thirteen years. There was every reason to think these patients were permanently cured, although one patient did have a recurrence and died between five and six years after the radical operation. (19) In spite of the high primary mortality, the end results in those surviving the operation encouraged us to continue with the procedure in suitable cases.

The Problem of Heat As a Method of Treatment in Inoperable Uterine Carcinoma. — Dr. JAMES F. PERCY of Galesburg, Ill., said there were three stages to be recognized in the development of the cautery in the treatment of carcinoma of the uterus: (1) where it was merely used to stop hemorrhage and limit offensive discharge; (2) in the galvanocautery excision of the cervix uteri, developed by the late Dr. John Byrne of Brooklyn, N. Y.; in this technique a high degree of heat was used sufficient to cut the tissues; (3) in the dissemination of a coagulating degree of heat through the widest possible area of the cancer mass, with no attempt at immediate excision of the parts. The technique of Byrne was not designed for the advanced inoperable cancer patient, the one in which the uterocervical junction was fixed, with extensive malignant and inflammatory infiltration of both broad ligaments and the parametrium. As classified to-day, Byrne operated only in the first stage of cervical cancer involvement. Dr. Percy stated that his technique brought the practitioner back to the days before Byrne, to the treatment of the otherwise hopeless case, and in addition he stated that his technique opened up new possibilities in the way of further improved results, in the type of case in which Byrne secured his best results. The author emphasized the point that the stage of operability with his present technique was easily 90 per cent., and he confidently expected that the stage of operability would be without limit in strictly pelvic cancer. He would not have the practitioner believe, however, that the ideal was mere operability. Back of it all was the hope and promise of results never before obtained by any method so far developed in that disease which had always stood as a synonym for incurableness—pelvic cancer. In conclusion, he reemphasized (1) that the Percy technique, so-called, was not a cautery operation. He removed nothing. The tissues following the application of the moderately low degrees of heat were literally coagulated and slowly dissolved. It usually took two weeks for a healthy granulating surface to appear beneath the gradually dissolving mass of inert cancer debris. (2) The operation of Byrne was a high galvanocautery incision of the cervix. There could be but little penetration of heat. Byrne recognized this when he advised that the surface left after the removal of the gross mass be seared over with the cautery knife, in order to get all the heat penetration possible. But Byrne never thought of applying heat to the degree of obtaining penetration sufficient to render movable the fixed tissues in the pelvic basin. If the fixed tissues, malignant and inflammatory, were not made freely movable, as they were normally, the heat penetration had not been sufficient, and, therefore, was ineffective. (3) To coagulate a large mass of uterine cancer required from thirty to sixty minutes, and if the broad ligaments still remained stiff or fixed, an additional ten minutes. (4) In the author's effort to emphasize the importance of avoiding the burning temperatures he feared that he had led many surgeons to the opposite extreme, and that they were trying to destroy the activity of an inoperable mass of cancer with a temperature so low that days, rather than hours, would be required to make the heat effective. Byrne fried the tissues; whereas the author broiled or pasteurized them. The Byrne technique was based on the use of heat as an acute process; while the author's was not acute, but chronic, both as to time and degree. Heat, more heat, and yet more heat; but heat, not fire; broiling, not frying; not roasting, but curdling; pasteurization, not desiccation; coagulation, not carbonization. In its practical application the whole technique could be summed up in the one statement: that one should not carbonize the tissues, for in the degree that this was done, in that degree was heat penetration inhibited; and heat penetration was the vitally essential thing.

High Heat Versus Low Heat in the Treatment of Cancer of the Uterus.—Dr. HERMAN J. BOLDT of New York City said that he had expressed himself fully on the relative value of high degree of heat compared with low degree, heat as a palliative therapeutic agent in the advanced stages of cancer of the uterus, in an article published in the *American Journal of Obstetrics* in the January (1916) issue, and judging from the communications he had received from physicians who had had experience with the treatment his position was amply justified. It was also corroborated by another autopsy, in addition to the one he had, by Dr. F. W. Bancroft of New York. He did not wish to detract from the usefulness of low heat, but it should be reserved principally for a second application, after rapid destruction had been accomplished with high heat, and the charred eschar that was caused by the high heat had been thrown off; and for those cases in which the cancer had so far advanced that the proper application of high heat would endanger the bladder or rectum. The danger from secondary hemorrhage was not less with low heat than with high heat. No evidence had been presented that showed the superiority of one method over the other. Heat, properly used, and applied in selected cases, sometimes gave remarkable good palliative effects; but it had been conclusively shown that cancer cells were not destroyed any appreciable distance from the surface of application, certainly not deeper with low heat than with high heat. This was proved by the examination of tissues procured at the autopsies mentioned. Dr. Charles Mayo, when discussing the paper alluded to, published in the *American Journal of Obstetrics*, asserted that the proof of the deep destruction of low heat was shown in cases that had been operated upon in the Mayo clinic, lay in the fact that at the time of cauterization the disease

had too far advanced for the patients to be operated upon radically, but later the uterus became mobile and was extirpated, and when these uteri were examined by the pathologist, he failed to find any evidence of malignant disease in them. This hypothesis was not acceptable to Dr. Boldt as valid proof, since the mobility might have become impeded by an inflammatory process which, as the result of the heat treatment, became dried out, as it were, and mobility of the uterus resulted; a result seen also when high heat was used. The inflammatory infiltration might subside, out the carcinomatous infiltration remained. To disprove this it was necessary for the operator, when the abdomen had been opened, to remove a part of the suspicious infiltrated area in the pelvis a reasonable distance away from the cervix, and have it examined by a competent pathologist. If that showed cancer nests, and the uterus became mobile subsequently, so that a radical operation might be done, and the specimen then removed by a radical operation failed to show cancer elements in the parametria, we were in the position to grant the deep destruction of cancer elements by the heat applied, but not until such proof had been shown. Attention was called to those instances in which recovery followed when a simple extirpation of the uterus had been done, despite some parametrial infiltration, and in which, after a period of a few months a reexamination failed to show any evidence of infiltration. He recalled two such cases.

Abdominal Myomectomy and Hysteromyomectomy by Morcellation.—Dr. CHARLES G. CHILD, JR., read a paper with this title in which he drew the following conclusions: The advantages of myomectomy or hysteromyomectomy by morcellation were many. The original morcellation by the vaginal route enjoyed great popularity because of the smoothness of the subsequent convalescence and freedom from postoperative complications, both immediate and remote. The abdominal removal of these tumors by morcellation now that we had to-day improved our abdominal technique gave just as smooth a convalescence and just as great a freedom from complications as was secured by the vaginal operators in the past. The advantages of the technique which he described were considered both from the point of view of the patient and of the surgeon. To the patient it afforded greater safety, a shorter and a smoother convalescence. This was by reason of the fact that as the surgeon worked practically extraperitoneally the intestines were kept out of the way without recourse to laparotomy pads; thus was the intraperitoneal traumatism minimized and postoperative shock, distension or peritonitis was seldom, if ever, seen. In hysteromyomectomy the danger of secondary hemorrhage from slipped ligatures on the broad ligaments was very materially decreased because of the ease and safety with which the relaxed broad ligaments could be ligated. The smaller incision and the stronger resulting scar, especially when the transverse incision was used, reduced to a minimum the danger of hernia. The high percentage of primary union resulting when the transverse incision was closed with non-infectible suture material, meant a much shorter hospital residence. A large granulating median line incision, where primary union had not been secured, meant a prolongation of the convalescence by many weeks, with a good prospect of a subsequent hospital stay when the ventral hernia, almost certain to occur in such a case, was operated upon. The advantages to the surgeon were that during the greater part of the operation the tumor was in contact with the abdominal wall, and the work was extraperitoneal. Thus was the surgeon able to see definitely each pathological condition as it arose and to take the necessary time to meet the indication, for by this technique the length of time which the patient was under the anesthetic was not nearly of the importance that it was when a large median incision had been made with all the consequent exposure of intestines, and use of laparotomy pads that went with the older technique. In hysteromyomectomy the ease with which the broad ligaments could be ligated, and the cervix removed when a complete hysterectomy was necessary was very marked. Although the transverse suprapubic incision might be so small as to handicap many an operator at the start, still as skill in anything was acquired only by repetition, so here with experience one became quickly proficient.

A Study of the Pathology in Its Relation to the Etiology With the End Results of Treatment of Sterility.—Dr. JOHN OSBORN POLAK of Brooklyn, New York, gave a personal review of 798 cases—histories of patients from his private practice, and analyzed the many etiological factors which had entered into the causation of sterility. He discussed the individual case based upon an etiological diagnosis, and finally summarized his end results. This study had shown (1) that a very large number of cases of sterility applying for relief had no chance whatever of becoming pregnant, as the pathology was such as to make conception impossible. (2) That the male was largely responsible for the poor results in treatment. (3) That there was a definite chemico-pathological factor in conception, at present unexplainable, which was a cause of preventing conception. (4) That operative procedures on the uterus, except amputation of the hypertrophied portion, had but a slight influence on the end results in the treatment of sterility; and (5) each case must be individualized and both contracting parties carefully studied before any treatment was inaugurated.

Rupture of the Scar Following Cesarean Section.—Dr. PALMER FINDLEY of Omaha gave a survey of the literature on this subject with a digest of case reports for the purpose of determining whether or not one cesarean section called for another in the event of a subsequent pregnancy, and then drew the following conclusions: (1) A perfectly healed cesarean wound might be relied upon to resist the forces of labor, but in view of the fact that the integrity of the wound was an unknown factor in all cases, he was constrained to exercise the utmost caution in the conduct of every case of pregnancy and labor following cesarean section. (2) Failure to secure perfect healing was accounted for by departure from the principles of suture proposed by Sanger and by septic infection of the uterine wound. If we were to obtain the uniformly good results in respect to wound healing that were secured in the decade following the introduction of the Sanger method of suture, we must not deviate from these principles. (3) The possible existence of latent gonorrheal infection might defeat the most painstaking efforts to secure perfect wound healing; hence it followed that the healing of a cesarean wound was always an uncertain factor. (4) When cesarean section had been followed by a fever course, the uterine wound should be regarded as insecure in the event of a subsequent pregnancy, and should call for a repeated cesarean section at the onset of labor. (5) Sterilization and hysterectomy should replace conservative cesarean section when infection was known to exist. The alternative invited faulty wound healing, if not more disastrous results. (6) Transverse fundal, extraperitoneal and cervical incisions had not lessened the liability of rupture in subsequent labors, but, on the contrary, had probably increased the hazard. (7) The possibility of rupture of the scar following cesarean section did not justify sterilization, but rather called for the exercise of masterly control in the event of a subsequent pregnancy. All such cases should be hospital cases and labor should be anticipated by timely repetition of cesarean section at the onset of labor if the uterine wound was known to be defective, or if some cause for obstruction to the delivery of the child through the natural passage existed. Version, high forceps, uterine tampons, hydrostatic bags and pituitrin should never be employed in the presence of a cesarean scar. (8) We might conclude that in view of the evidence that not more than 2 per cent. of ruptures occurred in subsequent labors, we were not justified in voicing the slogan, "Once a cesarean section, always a cesarean section"; neither were we to rely solely upon the integrity of the uterine scar in any case. Furthermore, he would conclude that the liability of rupture was a real danger and should stand as an argument against the increasing tendency to widen the scope of elective cesarean operations.

The Constitutional Factor in Gynecology and Obstetrics.—Dr. CHARLES P. NOBLE of Philadelphia spoke on this subject and presented these conclusions: (1) The theory of environmental, constitutional hypoplasia or arrested development from unfavorable environment, operating at any period from the preconceptional state of dual life in the ovary and testis, to that of the youthful period in ontogeny, which was presented to the profession as a medical hypothesis in 1908, and which the writer believed to be proven upon human clinical and pathological evidence, was now shown to be equally supported by the clinical and the pathological facts of antenatal pathology, and by the facts of comparative pathology, and to be demonstrated by the facts of experimental teratology. (2) The wis-

dom of the fathers of medicine, as expressed in their discriminating analysis of the facts of the hereditary nature of the diatheses or dyscrasias, together with the theory of environmental hypoplasia, constituted the law of devolution in its relation to medicine. (3) In order to obtain a comprehensive understanding of the practice of medicine, it was necessary to reject such of the teachings of Virchow and of his followers as were fallacious, and to combine the clinical wisdom of the fathers of medicine, from Hippocrates down, with the known facts of experimental medicine and their correct interpretation, and thus to arrive at the true point of view from which to study and to deal with the clinical problems which were the concern of practitioners of medicine and of each of its specialties. (4) The constitutional factor in gynecology and obstetrics, as was equally true of the other departments of medicine, was the chief element in the clinical problems which confronted the practitioner in dealing with disease and with atypical organs and tissues and their functions. (5) The recognition, comprehension, and employment of the foregoing principles would greatly enlarge the powers of the practitioner of medicine in diagnosis, prognosis, and in therapy, and which would enable him to avoid many common, if not habitual, errors, and positively to substitute general nutritional and developmental measures for the local measures currently employed, and thus effect the cure, instead of the amelioration, of his patient's condition when due to environmental arrest. Further, it would enable him to give scientifically based advice as to methods of living when the biological type of the patient was recognized; to promote the development of environmentally arrested patients, and to enable them to maintain their health by living within their particular potential or capacity to produce energy, instead of attempting to live as was physiological for typical individuals, but which would cause disease in the arrested or hereditary and environmental devolutes. (6) There remained unsolved two problems: (1) the process or mechanism whereby atypical morphology and function of environmental origin in ascendants became, at least, hereditary in descendants. Apparently its solution would be found in the facts of the maleficient consequences of urbanization in human stocks, which escaped extermination by degeneration and disease, and the variations and adjustments which ensued, whereby acquired immunity was attained; and similar facts concerning the consequence of the long continuance over generations of other unfavorable environment, such as insufficient nourishment, malaria, the hookworm, and food deprived of some element necessary to nutrition, or so mistreated as to be relatively poisonous. It might become demonstrated by subjecting short lived animals to definite, unfavorable environment, for twenty or more generations, and observing and correlating the facts thus obtained. Facts from biology as to species of animals and plants subjected for generations to inimicable environment would also aid in the solution. (2) The eradication of degeneracy and its prevention would probably find its solution in the development of euthenics and in the segregation, or the sterilization, of individuals manifesting the more marked degrees of degeneracy, more especially of the hereditary types.

A Résumé of Results in the Radium Treatment of 347 Cases of Cancer of the Uterus and Vagina.—Drs. Howard A. Kelly and Curtis F. Burnam of Baltimore said that after seven years' experience, and with a full knowledge of similar work in other parts of the world, they could now say without hesitation that the use of radium in sufficient quantities greatly enhanced the chance of permanent recovery of patients with uterine and vaginal cancers. In early and good operable cases the use of radium combined with operation added greatly to the prospect of recovery without a recurrence. This was shown in a series of twenty such cases in which they had as yet seen no recurrence. The most remarkable fact about the radium treatment of uterine and vaginal cancers was that it often cleared up those cases which had extended too far locally and became firmly fixed to the pelvic wall; in other words, in a class of cases which were utterly inoperable. They had had 327 patients, including borderline cases, cancers fixed to the pelvic wall, great massive cancers choking the pelvis, and many with general metastases, where the radium was used only to afford relief; and yet over 20 per cent. of this remarkable group had been apparently cured. They did not pause here to dwell upon the great alleviation afforded a large number of those who were not cured, but where discharge stopped, pain ceased, and health was built up. Their conclusion then was that radium had come to stay and was a most efficient agent in treating these cancers of the uterus and vagina.

X-Ray Treatment of Uterine Hemorrhage.—Dr. Robert T. Frank of New York City said that *x*-ray treatment was indispensable in gynecology, but under strict indications and limitations. The rays worked mainly by destroying ripening ovarian follicles, primordial follicles showing great resistance. When no ripe follicles were present, menstruation ceased. In fibroids there might also be a direct effect on the tumor. Fractional exposure implied frequently repeated treatments of small amount. This took more time, but permitted of finely graded dosage. Intensive treatment by use of small multiple fields permitted of rapid attainment of amenorrhea. The rays could be used in all functional hemorrhages (menorrhagia or metrorrhagia) in which expert examination revealed normal pelvic organs, and in which the curettings were free of malignant changes. This saved the uterus of adolescents and women in their sexual ripeness because the bleeding could be "foned down." It also saved women in the pre-climacteric age from operation, if they were bad operative risks. The writer used *x*-ray in about 5 per cent. of fibroids. Only 45 per cent. of fibroids required any treatment. Bleeding was most readily checked by raying. In order to permit of the safe employment of *x*-ray, the writer postulated that no cases should be rayed in which a suspicion of carcinoma or sarcoma could be entertained, that no complications, such as ovarian or adnexal tumors were present, that no urgent symptoms were present. This limited the treatment to clear cases of uncomplicated fibromyoma. Preference should be given to the rays when extreme psychical unrest or severe cardiac, renal or pulmonary disease contraindicated operative measures. The expense entailed by raying precluded its use except in well-to-do patients or in endowed institutions.

Precancerous Changes in the Uterus.—Dr. William S. Stone of New York City pointed out the evolutionary character of the different types of cancer of the uterus as beginning in definite benign lesions, such as erosions, leucoplakia and glandular hyperplasia, which showed variable quantities and qualities of epithelial overgrowth and metaplasia that might differ little from the regenerative activity observed in the benign lesions, or after a longer or shorter time might show atypical features that were differentiated with difficulty from the alterations we knew typified malignant neoplasm. To such pathological changes the author thought the term precancerous might be appropriately applied, as they appeared to represent changes that were neither cancerous nor non-cancerous, but were in the stage of becoming cancerous. Their relation to the development of a cancerous growth was shown by the fact that their morphological features included, in different combinations of quantity and quality, the numerous histological criteria upon which the diagnosis of a fully established cancer was made, lacking only in some instances the features of destructive activity and purpose. The strongest support of this conception was derived from the reproduction of types which were seen in the different stages of their progress. In the author's material, for example, he found the atypical features of a healing erosion determined by the original type of the lesion—simple, papillary, follicular, and the atypical types again reproduced in the different types of fully established uterine cancer. There were atypical erosions which were prototypes of either an epidermoid cancer or a papillary adenocarcinoma. There were leucoplakias which were prototypes of adult acanthomas. There were glandular hyperplasias which led to adenoma or adenocarcinoma. Finally, there were focal areas of leucoplakia, combined with adenomatous hyperplasia which might well furnish an origin for tumors designated as adenoacanthomas. In short, for each type of fully developed carcinoma there was a corresponding type of benign and intermediary change. The literature had been critically reviewed, showing increasing evidence confirmatory of the sequence of benign lesions in the uterus and cancer, but the efforts to define their histogenetic relation had been limited to a few writers. To more fully verify the assumption that morphological features of intermediary stages existed, a closer cooperation between the clinician and the pathologist would be required. For the present, it was no argument against such an assumption because no tumor process was present or followed in a given case. The evidence in the literature was already suffi-

cient to show that a fully established cancer might exist for a certain time without giving gross evidence of its presence, and numerous cases were recorded in which the curette had completely removed the disease. There was no reason to assume that precancerous changes without treatment must always develop into malignant growths. Different types of fully established tumors had a different capacity to grow and destroy rapidly or slowly, and it did not seem reasonable to assume that a developing cancer had the same momentum that a fully established tumor possessed. In the study of beginning cancer of the uterus several authors had directed attention to the fact that a certain type of early cancer might spread superficially over a wide area before showing marked invasive features, and it had occurred to the author that such a mode of growth might account in some measure for the extent of the process before it received the attention of the clinician. With the description of the author's cases there were sufficient clinical data to show the practical side of the problem, that the decision regarding the proper therapeutic procedure in such cases should be assumed by a competent clinician.

Painless Labor.—Dr. J. CLIFTON EDGAR of New York City pointed out that shock from the pain of labor in the highly civilized neurotic woman must be reckoned in general child-bed mortality. Painless labor in these women was a life-saving measure. The problem was the control of the pain in the first stage, the longest stage, after lasting a day or more. For the moment there was no ideal single method of painless labor. The only absolutely painless labor was one terminated by surgical means with complete anesthesia. Conditions would always arise, for example in early rupture of the membranes in which the necessity for painless labor would demand such surgical termination. The most satisfactory painless labor method of the moment combined opium and antispasmodics for the first stage, with possible vapor narcosis towards the end of this stage; vapor analgesia and anesthesia for the first and terminal parts of the second stage respectively. The narcosis aimed at should, until the perineal stage, be analgesic and not anesthetic in character, whether by drugs or vapor—a difficult or impossible object to attain unless one had had considerable experience. In analgesic work, there was the tendency of the patient coming out from under the influence of the gas and to suffer from the effects of shock due to the acuteness of the suffering, or of anesthesia being produced with its dangers in the hands of the novice. To sum up, nitrous oxide-oxygen analgesia or "obstetric" ether or chloroform should be used for the second stage, pushed to anesthesia for the perineal stage; possibly forceps delivery with vapor anesthesia to eliminate part of the second stage. Nitrous oxide-oxygen analgesia or anesthesia was superior to any other during labor because of its oxytocic action. Eventually an established method of painless labor might be related to public health questions. Lessening or abolishing the pain of labor might in the future limit birth control and criminal abortion. Drug addiction, after a prolonged drug narcosis in the neuropathic, was a possible contingency. The dangers to the newly-born child were negligible when drug narcosis was limited to the first stage.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held April 13, 1916.

DR. ROYAL STORRS HAYNES IN THE CHAIR.

Meningococcus Meningitis with Unusual Hemorrhagic Symptoms.—Dr. C. T. SHARPE reported this case, which occurred in a child showing very severe symptoms of meningitis. In addition to the symptoms typical of meningococcus meningitis, hemorrhagic areas appeared at various locations on the surface of the body. The bacteriological examination of the blood from these lesions revealed the presence of the meningococcus. Dr. Sharpe said he believed that this was the first instance in which the meningococcus had been isolated from a skin lesion. He exhibited lantern slides showing the appearance of the lesions.

Dr. HENRY HEIMAN said this case was of extreme interest, and he had never seen anything just like it, one so severe. If it had occurred during an epidemic one would have said that it was a fulminating case, or if there had been a number of similar cases one might have thought they were due to a particularly virulent strain of meningococcus, but this was the only case, and he could only explain it on the theory that there was a low degree of resistance in the individual. He did not believe that the injection of serum into the blood would have been effective in this case as the child was lost from the beginning.

The Deficiencies in the State Law Regulating Overcrowding in Institutions for Infants and Children.—Dr. THOMAS S. SOUTHWORTH opened the discussion. He said that it was admitted on all sides that the mortality among young infants placed in institutions was much greater than it should be, and greater than if the infants remained at home. Boarding out had been suggested as a means of relief, but while boarding out showed much better results than those of the poorest institutions, the results did not notably exceed those of the best institutions. Even if it were desirable institutions could not be done away with at once. Overcrowding was one of the fundamental factors which was definitely contributory to the mortality, but which could be remedied. Overcrowding was permitted and indorsed by their present inadequate and loosely drawn State law which, for lack of anything better, was applied to children of very divergent ages, conditions, and needs, and was largely robbed of whatever value it might possess by a "joker" clause. Chapter XLV of the Consolidated Laws defined the application of the law in question as follows: "To every institution in this State incorporated for the express purpose of receiving of caring for orphan, vagrant, or destitute children, or juvenile delinquents, except hospital." This law went on to say: "The beds in every dormitory in such institution shall be separated by a passageway of not less than 2 feet in width, and so arranged that under each the air shall freely circulate, and there shall be adequate ventilation of each bed, and each dormitory shall be furnished with such means of ventilation as the local board of health shall prescribe. In every dormitory 600 cubic feet of air space shall be provided and allowed for each bed or occupant, and no more beds or occupants shall be permitted than are thus provided for, unless free and adequate ventilation exists approved by the local board of health, and a special permit in writing therefore be granted by such board." The inference was that this law was framed to regulate the sleeping quarters of asylum or reformatory institutions for older children who might reasonably be supposed to spend a considerable part of their time in other quarters during the day. There was no trace of implication that it was intended to apply to infants or to wards in which more or less sick infants lived practically all the time, both day and night, during a very considerable part of the year. It would appear that it was the intention of the framers of this law that there should be not less than 600 cubic feet of air space per inmate, but this intention was nullified by the final or "joker" clause, which was perhaps appended as a compromise. This clause granted to any local board of health in the State the power to issue permits for any larger number of inmates under certain conditions as to "free and adequate means of ventilation." Such adequate means of ventilation should exist. When it came to the practical working of the law in New York City one found that framed permits were hung upon the walls of each ward stating the number of infants allowed therein. Permits were until recently granted by the Board of Health based upon the number of square feet of floor space, allowing about 50 square feet or slightly over, for each inmate of the ward. This had recently been changed to cubic feet, allowing about 500 cubic feet per inmate, and affording at times less than 50 square feet of floor space in certain institutions, depending upon the height of the ceilings. Dr. Southworth said he had been informed authoritatively that this amount might be and was reduced legally as low as 200 cubic feet per inmate in certain other types of institutions covered by the law, and there was nothing to prevent a further reduction below 500 cubic feet in wards for infants. Whether the 600 cubic feet of air space per inmate was or was not adequate for the dormitories or sleeping quarters of older and presumably well children he was not here to discuss, but he did with all earnestness contend that the application of the law for the lack of a better, to wards containing infants under two years of age and especially bottle-fed infants under one year of age, since an allowance of only 500 cubic feet, and perhaps less than 50 square feet of floor space per infant, tended directly to increase both the morbidity and consequently the mortality among such infants,

a mortality which, in part at least, was preventable. The origin and authority for the 600 cubic feet standard appeared to be lost in obscurity, but judging from the answers received in response to a questionaire sent to the American Pediatric Society and compiled and published in the Archives of Pediatrics, September, 1915, such space allowance fell far short of the 1,000 cubic feet demanded by the majority of pediatric opinion throughout the United States. In all except possibly the most modern and enlightened institutions, bottle-fed infants who remained for any considerable length of time did not continue to be well infants, even though they were admitted as such. The wards in which such infants were cared for demanded the larger nursing staff and adequate cubic air space of sick wards. In whatever type of institution they were situated they were to all intents and purposes hospital wards, not dormitories. Overcrowding meant a proportionately decreased care of the individual infant and undercare made for an increased mortality. With exactly the same methods of feeding infants that had been doing well with ample air space, when owing to new admissions the point of overcrowding was reached, ceased to gain, some lost rapidly, and there were a number of deaths until the census of the infants was again reduced. In short, modern feeding methods failed, or availed only temporarily, to prolong the lives of infants where overcrowding was permitted. With our present knowledge it was not necessary to argue that infections, both the more subtle respiratory types and the openly contagious types, were more readily spread by permitting closer proximity of the infants' cribs. The question might be asked: "Why, if this overcrowding so manifestly contributes to the mortality, are not steps taken by the physician of each institution to reduce the numbers in the wards?" The answer was that it was obviously difficult to convince lay managers that the permits issued by recognized authorities concerned with the enforcement of health regulations did not represent the last word in the most enlightened pediatric opinion concerning the needs of infants. The Pediatric Section of the Academy of Medicine had been asked to review this matter as a section and from the pediatric standpoint. Dr. Southworth said that he would suggest that the law be revised; that certain sections should be framed for orphan asylums, reformatories, and older children; and separate sections framed for young children and infants; that provision should be made for ample space in sick wards; that wards containing bottle-fed infants under eighteen months of age should be specifically classed as sick or hospital wards; that the amount of cubic space allowed to each of these main groups should be based upon modern pediatric opinion, and that there should be no qualifying clauses permitting the purport of the law to be nullified to suit individual caprice; that after basic space, which was sufficient with the windows closed had been specified, further provision might then be made for inspections and enforcement by local authorities, with a view to assuring reasonable employment of the usual available means of ventilation. In closing, Dr. Southworth stated that he did not claim that additional air space was a cure-all which would remedy all the difficulties in rearing infants in institutions, but he did maintain that increasing the cubic air space was the surest, most direct, and most feasible way of correcting a number of the evils of institutional life.

Dr. CHARLES GILMORE KERLEY said that the mortality of young children depended on so many other factors in addition to that of cubic air space that he felt that this was comparatively speaking but a small part of the subject. If the air was undergoing active ventilation a smal cubic air space might answer very well. One of the worst features met in institutions was that there was but one room for a group of children, and there they must play, eat and sleep, and this was the factor that did not obtain in ordinary dwellings. Another matter was with reference to an adequate system of ventilation. In his experience with systems of ventilation he did not know of one that really did ventilate; when one wanted ventilation he still had to resort to the open window.

Dr. HENRY DWIGHT CHAPIN said that Dr. Kerley had brought out the two points which he would emphasize. We might have 1,000 or 10,000 cubic feet of air space, and if everything was shut up the supply of air might be insufficient. The essential factor was to have an adequate supply of freely moving fresh air and then the cubic air space was not so important. It seemed that the best way of dealing with institutions for infants was to abolish them as far as possible. It had been said that lay boards made the rule and doctors followed them. The doctors should say that if conditions were not improved they would no longer remain on the staffs of such institutions. We might as well recognize the fact that the trouble was a lack of force on the part of the doctor.

Dr. FLOYD M. CRANDALL said this question had been brought up for very definite reasons, particularly for opinions with reference to accommodations for infants and children in institutions as measured by cubic air space. This was what the discussion should bring out. The question had come up whether the Public Health Committee of the Academy of Medicine should take up the modifying of this law. The question should be considered by pediatricians first, and the doctors who discuss it should bring out something definite and tangible.

Dr. HAYNES suggested that the best way of obtaining the opinion of the members of the Section would be to appoint a committee which should submit a *questionnaire* to the members individually and then present the results to the Public Health Committee of the Academy.

This suggestion was acted upon.

The Hospital Control of the Infectious Diseases of Infancy and Childhood.—Dr. DENNETT L. RICHARDSON of Providence, R. I., read this paper by invitation. He presented some facts on the transmission of contagious diseases learned by hospital observations. He said it was pretty well established that the sources of any infectious disease were three, namely, the clinical case, the missed case, and the carrier. The disputed questions related to the methods by which the virus found its way into the healthy person. Formerly the rôle of air infection was given more attention than the avoidance of infection by contact. Through the observation of some of the French investigators, the conclusion had been reached that the infectious diseases were seldom air borne, and that isolation of the patient was not complete unless rigid antisepsis was carried out. The practical results obtained at the Pasteur and other French hospitals had shown that the employment of antiseptic nursing had made it no longer necessary to house different diseases in separate pavilions. In consequence of this there had developed several methods of construction by which one might obtain physical separation of patients suffering from different infectious diseases and yet treat them in the same ward. These systems were: (1) The cubicle system, having its origin in the Pasteur Hospital and consisting of single rooms, the partitions being complete or only partially reaching to the ceiling and arranged on both sides of a common corridor; (2) the barrier system, consisting of bed isolation of different diseases in a large open ward; (3) the cellular block plan as constructed at the Plaistow Hospital, consisting of two rows of rooms, back to back, with glass partitions between them, each room leading to an open veranda on either side of the building. The statistical records of London hospitals into which these systems were introduced demonstrated the success of aseptic nursing. They showed, however, that measles and chickenpox were the most difficult of the infectious diseases to care for by aseptic nursing. In March, 1910, aseptic nursing was first undertaken by the Providence City Hospital, which, through the efforts of Dr. Charles V. Chapin, who had made a study of contagious disease hospitals abroad, was constructed in accordance with the theories of medical asepsis. In this hospital patients suffering from contagious diseases were accommodated in three pavilions, arranged parallel and containing about 140 beds. Two of these buildings were duplicated, each floor being so arranged that about one-half the patients could be placed in rooms off the central corridor and containing from one to three beds each, while there was a convalescent ward with fourteen beds at the south end of the building. At the present time one of these duplicate buildings was devoted to scarlet fever. The first floor of the other building housed the diphtheria patients; the second floor was used for an isolation ward in which various infectious diseases except measles and chickenpox were cared for. These latter highly transmissible diseases were not included because the nursing in these buildings was largely done by pupil nurses. The third building provided for the care of any infectious disease, including smallpox. Every room was provided with a lavatory, where the water must be turned on by forearm or foot levers, and where nurses and physicians must wash contaminated hands in running water with soap and a

scrub brush. Immersion in an antiseptic solution was also required after such diseases as measles and chickenpox and smallpox, and very septic cases of other infectious diseases. Elaborate construction alone was quite unable to prevent cross infection; proper management was of far greater importance. The latter resolved itself into proper admission of patients to prevent mistakes of diagnosis, securing a history of other infectious diseases in the home, active and intelligent observation of the patients for signs of secondary disease, careful attention to the health of all employees, and the proper and efficient sterilization of hands, utensils, and linen between different infectious units. At the time of admission all doubtful cases were isolated until the diagnosis was clear. Nurses were impressed with the importance of asepsis and taught the details of its administration. When a patient was ready for discharge he was given a soap and water bath and shampoo. This bath was given the day before discharge, and the patient was then put into a clean room set aside in each ward as a discharging room. When the mother came for the child clean clothes were put on him, and if he presented no symptoms after a careful examination he was taken away. The rooms had never been fumigated since the opening of the hospital, but the floors and furniture, and in the isolation wards, the walls within easy reach, were washed with soap and water. A careful record had been kept of the room or rooms occupied by each patient, and he had never been able to trace any cross infection to this source. Infected linen was collected under aseptic precautions and placed directly into the washers, where it was washed by boiling water and its sterility tested by cultural experiment. No sterilizing washers were used. All the elaborate technique of caring for the patient was supplemented by careful supervision of the nurses and the entire hospital personnel. Resident physicians wore white suits. Over their shirts they wore a short-sleeved washable vest, outside of which was worn the usual white coat. When visiting patients the coat was removed and a gown was worn only when making careful physical examinations. The doctor always scrubbed his hands when going from one infectious disease to another. From March 1, 1910, to January 1, 1916, 6,748 patients had been discharged from the hospital. Among these there occurred 166 instances of cross-infection. The diseases contracted were as follows: measles, 48 instances; chickenpox, 78; scarlet fever, 19; diphtheria, 10; rubella, 4; whooping cough, 4, and mumps, 3. The total incidence for the whole hospital was 2.4 per cent. If from the total number of discharges 2,029 adult patients suffering from tuberculosis and syphilis were subtracted, leaving 4,689, the incidence was 3.5 per cent. There had never been a cross-infection between the tuberculous and syphilitic patients. Nearly all instances of infectious diseases arising among employees had occurred among pupil nurses. Aside from the nurses, among 229 employees, only five contracted an infectious disease. These results demonstrated that rigid asepsis was of primary importance. Hospitals for infectious diseases and for children should not have wards of over six to ten beds, and should have sufficient smaller units to accommodate all patients for an observation period. Conservative and accurate diagnosis of patients on their admission and careful supervision would prevent the entrance or continued residence in the same unit of patients suffering from more than one transmissible disease. Among forty-two house officers serving during the period under consideration, two developed diphtheria and one both mumps and rubella.

Dr. George Draper discussed the hospital care of poliomyelitis. He said that a most notable feature with reference to Dr. Richardson's paper was that no mention was made of poliomyelitis. There were two reasons why there were so few cases of these cases in this great institution: First, poliomyelitis had essentially a rural distribution, and, secondly, sporadic cases in the city unusually came into the large general hospital. The care of poliomyelitis in such a hospital as Dr. Richardson had described was a simple problem. The management of this disease was essentially the same as that of scarlet fever and diphtheria. Perhaps particular stress should be laid upon caring for secreta and excreta. There had been a number of instances of cross-infection recorded in Sweden, and among nurses a number of cases had been reported in Europe and America. Their protection, as far as our present knowledge went, depended upon the rigid care of the hands, nasal passages and mouth. The control of the disease in hospitals must be similar to that of other diseases. Possibly in addition there hould be special care given to the nose and throats of contacts. The attendants should use a spray of peroxide solution, or of menthol in oil. Quarantine was at present their best defense in the control of the disease in the community. While most of the means of transmission of poliomyelitis had been determined, some apparently still remained hidden. It had not yet been determined why one infant in a family contracted the disease and not others in the same family; why some sections of a community had a number of cases and others not, and why at another time it would be found in that section of the community which before was free. The part played by abortive cases and healthy carriers must still be cleared up. Contacts must be thoroughly controlled and likewise the carriers and the patients, and the same rigid quarantine must be maintained as in other infectious diseases, though it had not been definitely demonstrated that the virus found in the nose and throat of healthy carriers transmitted the disease. The duration of the activity of the virus in convalescent patients was important. A case had been reported of a child having two attacks of the disease two years apart, and five months after the second attack it still harbored the virus. In monkeys the virus usually disappeared in five or six weeks, but in certain individual monkeys it might persist four or five months. The incubation period of poliomyelitis was normally two to seven days, but there might be a very long latent period, as in one case which had been recorded of a young woman who was committed to prison and who developed poliomyelitis two months after her admission to solitary confinement.

Dr. Henry Heiman spoke of the epidemiology of meningococcus meningitis, and said that this presented features at times so strange and puzzling and so different from the characteristics usually associated with other contagious diseases that its contagiousness had been questioned by not a few observers. As a rule there was no regular progression or extension of the disease. It moved by leaps and bounds and struck haphazard. In considering the hospital control of infectious diseases from the standpoint of meningococcus meningitis, it was advisable to consider first the mode of transmission of the disease. It was well known that the disease was a communicable one, and that it occurred in epidemics. It was also endemic in New York, as were most of the other communicable diseases. It was generally conceded that the mode of transmission was by means of Flugge's droplet infection; that was, that the meningococcus was transmitted to the exposed mucous membranes of previously healthy persons. Meningitis might or might not be the result of this transmission, depending upon the susceptibility or resistance of the individual. A study of the natural history of the meningococcus made it improbable that the disease was transmissible through the agency of the atmosphere of lifeless objects, but from one individual to another. This did not necessarily mean from patient to patient, but it did mean that in most cases the source of contagion was a healthy or apparently healthy meningococcus carrier. Experiments had shown that there were from ten to twenty times as many healthy carriers as there were diseased carriers or patients. Therefore, in order to properly control the spread of meningococcus meningitis, they must devote their attention to prophylactic measures. In hospitals these measures were the gown, the hand brush, and disinfectants; and it would seem rational to add the usual measures, the gargle, and the cleansing of the naso-pharynx of the physician, the nurse, or of any one coming in contact with the patient. The disinfection of all the excreta of the patient, especially those of the respiratory tract, was of the utmost importance. Experience had shown that absolute quarantine in a hospital was not necessary, as transmission of the disease in hospitals was comparatively rare; however, the infection of nurses attending cases had been reported. School infections, though rare, had been reported by Bolduan and Goodwin and Netter and Debrè. The latter observed 10 cases, six of which attended a common school. Among 231 pupils in this school, 40 were found to be meningococcus carriers, that was, 21.21 per cent. Flugge reports that 70 per cent. of those living in close proximity of a meningitis patient became carriers. Netter and Debrè found 41.66 per cent. of those coming in contact with patients having meningitis became carriers during the months of March, April and May, while during June, July and August only 26.66 became carriers. It would not be

amiss to have occasional cultures of the nasopharynx taken from doctors and nurses attending cases of meningitis. Overcrowding in hospitals during an epidemic of meningitis should be avoided. The advisability of sending meningococcus meningitis cases to the hospital should be urged upon the public, not only for the sake of preventing the spread of the disease, but for better observation and better control of the disease by laboratory methods. If patients remained at home, they should be isolated, and intermingling between members of the family and the outside world restricted as much as possible. Children belonging to the family of the patient should not be permitted to attend school for about three weeks from the onset of the disease, unless they could be proved by bacteriological methods to be non-carriers. In concluding, Dr. Heiman emphasized the importance of the healthy carrier in the transmission of meningococcus meningitis, and said that attention should be directed to these almost as much as to the patients themselves. Prophylactic measures directed along these lines would probably help to lessen the dissemination of this disease.

Dr. WILLIAM H. PARK discussed the control of diphtheria. He said it was interesting to observe how a paper like Dr. Richardson's was received. Ten years ago they would have thought that the methods described were not efficient quarantine. They would have thought that caring for two kinds of infectious diseases with only a partition open at the top between them was not effective quarantine. As to diphtheria and the Schick test, a negative Schick test could be absolutely relied upon as evidence that an individual was immune to diphtheria, except in very young infants. Dr. Hess had had one baby that gave a negative Schick test and three months afterwards developed diphtheria. This was because in early infancy the child still had its mother's immunity, which it lost later. Dr. Park said their views with reference to active immunity had changed. They had found that about 90 per cent. of those who were given immunizing doses of toxin-antitoxin did not develop antitoxin for some weeks, so that in hospitals the production of active immunity was only of practical value for physicians and nurses, but for the protection of the patient they must still rely upon passive immunity. Up to the present time nothing had been discovered that was effective in the treatment of diphtheria carriers. A careful antiseptic toilet of the nose and throat simply covered up the bacilli and after a few days without treatment they again showed themselves. The only measure that seemed to be effective was the removal of the tonsils. The production of active immunity to diphtheria had a wide field of usefulness.

Dr. BERTRAM H. WATERS discussed the subject of whooping cough in relation to hospital control. He said it was rather difficult to speak on this subject since so few cases of whooping cough were sent to the hospitals. It was estimated that only about 50 per cent. of the cases of whooping cough were reported and only a very few of these came under the control of the hospitals. Whooping cough presented a rather difficult problem, and the Department of Health did not supervise cases of this disease because of the difficulty of obtaining early reports and since the period of infectivity of the disease was during the time before a diagnosis was made, and also because of lack of men and funds to carry out such work, all of these being needed to look after the more severe forms of infectious disease. At the present time they were considering the advisability of requiring a two weeks' quarantine for whooping-cough cases, that would cover the first week and aid in controlling the infection during the second week. Dr. Waters expressed the opinion that the use of the vaccine gave very promising results in immunity, as was shown by the work of Dr. Park and Dr. Hess.

Dr. ALFRED F. HESS, in discussing the hospital control of measles, said that this subject was particularly interesting because the mortality of measles in hospitals was so different from the mortality in the homes. The hospitals, however, were not so much to blame for their high mortality. They had found that about one-third of the hospital cases of measles were under two years of age. Again the mortality from measles was almost entirely due to pneumonia. During March they had had 25 deaths due to pneumonia; 21 of these cases were admitted to the hospital with pneumonia and four developed in the institution. In February there were 17 cases of pneumonia admitted and two developed the disease after admission to the hospital. The high mortality from measles and penumonia in contagious disease hospitals was largely due to the fact that they received the very severe cases, and that the very severe cases were transferred to the hospital from homes and institutions. Since there was no specific treatment for measles and penumonia, it might be advisable to direct their treatment to the pneumonia and give the patient the treatment for this disease. They had always been afraid of fresh air for cases of measles and shut these patients up, but when measles was complicated with pneumonia it would be well to make an exception and give the patient the benefit of fresh air. Furthermore, unless it was absolutely necessary, no case of measles under two years of age should be sent to the hospital. A mother would be willing to care for a child with measles if told that children with measles did better at home than in a hospital. They should get the cooperation of the community to keep these young children with measles out of the hospitals.

Dr. HAVEN EMERSON said that New York as well as the rest of the country was indebted to our teachers from Providence. The fact that the New York Department of Health had abandoned fumigation might be attributed to the teachings of Dr. Chapin. In their new hospitals for infectious diseases they had practically followed out his plans of construction with very slight modifications. When it came to confining infection to the individual they must establish the same teaching among medical nurses that they had been emphasizing in the training of surgical nurses, that was, they must be taught aseptic technic. If this were possible there was no reason why these diseases could not be treated in a department of a general hospital. If this could be done it would effect a great economy since it cost a great deal to keep up a large number of beds simply on the possibility that they might be needed at certain seasons. It would be a great economy if they could use these beds all the year around, and this could be done by absorbing the acute infectious diseases of childhood during the season when they were most prevalent, and then caring for chronic cases, such as tuberculosis and syphilis when the acute infectious diseases were less prevalent. Dr. Emerson also emphasized the desirability of having physicians teach the people to keep children under two years of age with measles at home. He said it was really a question whether they ought to be admitted under any conditions, certainly only when the home conditions were such that it was absolutely impossible to give them the first elements of decent care. There would always be a need, however, for some hospital that would care for measles in New York City. There was also the question of the advisability of admitting cases of whooping cough (and they would make every effort to admit these cases) when they occurred in a family in which there was a child under two years of age who would be exposed to the infection. Dr. Emerson also suggested that it might be proper to provide a hospital care for cases of gavus and ringworm, since a number of children lost a great deal of time from school on account of these conditions.

Dr. RICHARDSON, in closing, said that from what Dr. Park had said it seemed that their work was more or less misunderstood. They had a ward for scarlet fever and one for diphtheria, into which they had introduced other diseases occasionally. They also had three isolation wards for various infectious diseases. The plan of admission which they carried out was a process of filtration, keeping all the new patients in small units for a one-week period of observation. Their plan meant more to the small town or the small city that could not afford to have a hospital for each infectious disease. In a small city where there was a necessity for economy, this plan could be carried out if one knew the underlying principle, that was, that contact infection, infected human beings, and not environment, was the source of infection, and if they could control the contacts, the mild cases and the clinical cases, they could have much better control of infectious diseases.

Dr. HAYNES asked Dr. Richardson how his statistics with reference to cross-infection compared with those of other hospitals.

Dr. RICHARDSON replied that few American hospitals had published reports on that point. The only one he knew of was Dr. Auker of the St. Paul County Hospital; he gave the number of cross-infections and the number of cases of infectious disease among employees and nurses. This was the only report beside that of the Providence City Hospital in this country that gave this data, but some of the foreign reports

showed that for scarlet fever and diphtheria the number of cross-infections had been as high as 7 per cent.

Dr. KERLEY asked Dr. Richardson if he had had any experience with reference to the incubation period of scarlet fever.

Dr. RICHARDSON replied that the shortest incubation period he had known was thirty-six hours, and as to the other limit he did not think anyone knew. If a child came into the hospital with scarlet fever, and if at the end of four weeks it was necessary to detain him for a day or two, and then another child came in from the same family, one could not say whether he was infected by some other child at home—a mild case that had escaped detection—or whether the incubation period had been long, that patient having been infected by the hospital patient admitted four weeks before. Had the hospital case returned home, the second case would have been looked upon as a return case.

Books Received.

LOCALIZATION BY X-RAYS AND STEREOSCOPY. By Sir JAMES MACKENZIE DAVIDSON. Published by Paul B. Hoeber, New York, 1916. Illustrated. 72 pages. Price $3.00.

BACTERIOLOGY, GENERAL, PATHOLOGICAL AND INTESTINAL. By ARTHUR ISAAC KENDALL, B.S., Ph.D., D.P.H. Published by Lea & Febiger, Philadelphia and New York, 1916. Illustrated with 98 Engiavings and 9 plates. 651 pages. Price $4.50 net.

THE TREATMENT OF DIABETES MELLITUS, with Observations Upon the Disease Based Upon One Thousand Cases. By ELLIOTT P. JOSLIN, M.D. Published by Lea & Febiger, Philadelphia and New York, 1916. Illustrated. 440 pages. Price $4.50.

A MANUAL OF OTOLOGY FOR STUDENTS AND PRACTITIONERS. By CHARLES EDWIN PERKINS, M.D., F.A.C.S. Published by Lea & Febiger, Philadelphia and New York, 1916. Illustrated with 120 Engravings; 445 pages. Price $3.00 net.

A MANUAL OF FIRE PREVENTION AND FIRE PROTECTION FOR HOSPITALS. By OTTO R. EICHEL, M.D., Director, Division of Sanitary Supervisors, New York State Department of Health. Published by John Wiley & Sons, Inc., New York, 1916. 69 pages. Price $1.00 net.

DISEASES OF OCCUPATION AND VOCATIONAL HYGIENE. Edited by GEORGE M. KOBER, M.D., LL.D., Washington, D. C., and WILLIAM C. HANSON, M.D., Belmont, Mass. Published by P. Blakiston's Son & Co., 1012 Walnut St., Philadelphia, Pa. Illustrated. 918 pages. Price $8.00 net.

THE PRACTICE OF OBSTETRICS. Designed for the Use of Students and Practitioners of Medicine. By J. CLIFTON EDGAR, Professor of Obstetrics and Clinical Midwifery in the Cornell University Medical College, Visiting Obstetrician to Bellevue Hospital, New York City, etc. Published by P. Blakiston's Son & Co., 1012 Walnut St., Philadelphia, Pa. Fifth Edition, Revised. Twenty-second thousand. With 1316 Illustrations, including Five Colored Plates and 34 Figures Printed in Colors. 1067 pages. Price $6.00 net.

THE PRACTICAL MEDICINE SERIES. Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Vol. IV—Gynecology. By EMILIUS C. DUDLEY, A.M., M.D., and HERBERT M. STOWE, M.D. Series 1916. Published by The Year Book Publishers, 327 South LaSalle St., Chicago. 232 pages. Price $1.35.

THE CLINICS OF JOHN B. MURPHY, M.D., at Mercy Hospital, Chicago. Edited by P. G. SKILLERN, JR., M.D., of Philadelphia, August, 1916. Published bimonthly by W. B. Saunders Co., Philadelphia and London. Vol. V, No. 4. Illustrated. 771 pages. Price $8.00 per year.

STUDIES FROM THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. Reprints. Volume XXIV. Published by the Rockefeller Institute for Medical Research, New York, 1916. Illustrated. 515 pages.

Therapeutic Hints.

Simple Treatment for Cleansing in Otitis Media.—Coble recommends the following on account of the materials being found in every home as well as for the known antiseptic properties: Carbolic acid, minims 40-60; water, one quart. Where the perforation is large or the drum membrane almost destroyed, and the discharge has a foul odor, the following prescription has decided beneficial qualities:

℞ Boracic acid, grs. xx
Ethyl alcohol, ʒj

The canal must be first thoroughly cleansed with boric acid solution, dried, and then a diluted solution of the above dropped well into the canal and allowed to remain until the smarting ceases. A one to three solution should begin the treatment and the strength gradually increased until the original prescription is employed.—*Indianapolis Medical Journal.*

Gargle for Adults.—For an astringent and antiseptic gargle Coble recommends:

℞ Ethyl alcohol, ʒij
Cinnamon water, ʒij
Formaldehyde, ♏ij
Glycerin, ʒv
Distilled water, q. s. ad. ʒviij

Simple Rules for the Prevention of Chronic Diseases of Metabolism.—Greely, in discussing diabetes, offers these suggestions for rational living and the prevention of metabolic conditions: The training should begin for the child with the parents and continued until the son or daughter is able to control his or her own life: (1) Thorough mastication prevents indigestion, overeating, and bad teeth. (2) Thorough mastication does away with excessive drinking at meals and thus overcomes a tendency to avoirdupois. (3) The amount of starches, meat, and sugar in the diet should be reduced to a minimum and a corresponding increase made in the amount of vegetables and fruits eaten, especially in adults performing but a moderate amount of work. One cereal food is sufficient at each meal. (4) The final rule of health offered is to live more slowly, and to encourage every man, woman, and child to cultivate a hobby, a resource for happiness in their hour of need, when the real work of life must be suspended.—*Wisconsin Medical Journal.*

Simplest Cure for Scurvy.—Fruit juices, orange or prune, are the time-honored remedy for infantile scurvy, but the white potato has proved just as efficacious and within the reach of the poorest family. The proportion generally used is one tablespoonful of mashed potato to one pint of water, and added to the twenty-four hours' feeding of milk in place of the usual cereal diluent. The potato should be pared very thin and an average-sized potato when mashed covers the amount needed. The mashed potato can be added to the water in which it is boiled and thus all of the vitamines conserved.

Remedy for Carbuncles.—Apply collodion over hyperemic area except the central one-fourth inch space. Cut crucial opening in this space from center toward periphery and inject the following solution:

℞ Acidi carbolici sat., gtt. xx.
Glycerin, ʒij
Aqua dest., ʒij

Dress with sterilized gauze dipped in bromine, I—500, or chlorinated soda in 10 to 25 per cent. solution. Remove all sloughs.—*Medical Summary.*

THE PROBLEM OF REST OR EXERCISE IN THE TREATMENT OF PULMONARY TUBERCULOSIS; A PLEA FOR LESS ERGOPHOBIA.

By CHARLES L. MINOR,

ASHEVILLE, N. C.

In the treatment of pulmonary tuberculosis there are no more important measures than rest and exercise. On their wise and judicious use rests a large part of the success of our therapeutic measures. In the past a vast number of consumptives have come to their end directly through an injudicious use of exercise, and the advice "get a horse and ride out West" so frequently given thirty years ago was undoubtedly of more benefit to the undertaker than to the patient. Reacting from this rash and foolish use of excessive exercise, our profession have learned the priceless lesson that in the beginning of the treatment of tuberculosis rest is always indicated and the reclining chair and the cot have replaced the mountain climb and the horseback ride with the happiest effect. Twenty years ago many patients came to me suffering from the effects of excessive exercise. I recall two slender young Irish girls from a large Massachusetts town who called me in when one had fainted as the result of a five-mile walk. They were advanced cases of active tuberculosis with excavation, yet the only advice their home doctor had given them was to avoid doctors, to eat freely, and to walk as many miles daily as they could. This advice they had proceeded to carry out, with afternoon temperatures of 103° and over and with the result noted. By absolute bed rest their fever was brought down, their symptoms greatly ameliorated, and the activity in their lungs decreased, and while one was past any cure the other lived for many years a happy if semi-invalid life. Probably any of my auditors could duplicate such a history, but even among general practitioners, to-day there are few to be found who would give such advice. The profession have at last painfully learned that rest is good in the treatment of tuberculosis and patients get much more careful attention on this score than formerly. But doctors, like all other men, are prone to run to extremes, and, while I realize how heretical it may seem to say so, I find that to-day many men are tending to push rest to an unwise extreme. I see patients so indoctrinated by their medical advisors with the idea of the essentiality of rest that when they are discharged they are afraid to move, and they live a useless life, recumbent on the sofa, refusing to exert themselves in any way, and for all the good they are to themselves or the community they might as well have died rather than recovered, if such a life can be called recovery. Patients with normal temperature are kept flat on their backs laying up useless pounds of fat rather than turning that fat to muscle by judicious graduated exercises. Weight as weight and not as representing vitality and working efficiency is looked on as the summum bonum and good in itself, and such stall-fattened patients are only fit for the eternal quiet and contemplation of a Thibetan monastery.

If I were talking to a body of general practitioners I would not speak in this way, for they might misunderstand it, and it is far safer to overdo rest than to return to the former overdoing of exercise. But before a body of clinicians and specialists like this, I can speak freely and not be misunderstood, and for such I believe it is wise to stop a moment and consider in how far rest and in how far exercise are desirable in the treatment of pulmonary tuberculosis.

It is needless in studying this question to go back in the history of medicine to show how intelligent were the views of Hippocrates and Celsus, or to review the dispute between Brehmer, with his theory of the small heart in tuberculosis and the consequent need of active exercise, and the wiser view of his pupil Detweiler, who, seeing the bad effects of over-exercise, advocated recumbent rest. We need only go back to the time when our great American leader in Phthisiotherapy, Dr. Trudeau, as he has so graphically told in his autobiography, went in the 70's to the Adirondacks for his health, and, as we can now realize, wasted much of his superb vitality and his opportunity of permanent cure in over-exercise. By degrees, by the experience of his own case and that gotten with many patients, he was brought to use the rest he had so neglected, and among his followers, not merely in Saranac but all over our land (for he was verily the medical father of all American phthisiotherapeutists whether they had worked under him or not), we find a realization of the value of rest, a healthy fear of the danger of exercise, which in that day was most certainly justified.

The Adirondack recliner soon dominated the hygienic management of the disease, and many were saved who, had they exercised, would have been lost.

What is the basis for the success of rest? First, it lessens circulation and hence toxin absorption. Second, it lessens oxidation and lowers temperature and so decreases tissue waste. Third, it puts the diseased lung at rest. Fourth, it rests the heart. Fifth, it lessens cough and expectoration, probably because quiet decreases physical and pathological activity in the diseased foci. Sixth, it encourages weight gaining. Seventh, if properly managed, it helps to put the mind at rest.

Now, all these things are admirable, and, in

certain stages of the treatment, essential, but there comes a time when disadvantages show themselves and when too long continued rest ceases to be of value and becomes harmful.

When the temperature falls, when the afternoon figure is not over 99.4°, when the pulse slows, showing a decrease of toxin absorption, when strength is improving, when the trouble is less active and we desire to develop the compensating functtion of the healthy part of the lung by the quiet, deep breathing, or by judicious exercises, when cough and expectoration are much reduced and we can, therefore, assume that there is less ulceration and activity in the diseased area, when the patient needs the stimulus of hope and the encouragement of a positive proof of his improvement, when his gain of weight is marked and without exercise is apt to produce fat rather than muscle, then I believe we should take up exercise, not merely on the theory of Pattison, in which I concur, in order that the patient may undergo an autotuberculin treatment, but to prepare him, when he shall be restored, to resume his life in a normal way and not to be turned, as too many now are, into pulmonary hypochondriacs. Because it has been abused many men are afraid to mention the word exercise, just as bleeding was unjustly discredited from its one-time over-use, but exercise is just as essential in phthisiotherapy as is rest, and should be dominant in the latter months of any successful cure. Beginning with from one to five minutes, according to the case, and increased by from one to five minutes a day and guarded by a careful record of symptoms, fever, and pulse, kept by the patient, which the doctor should see twice a week, and stopped or decreased just as we would tuberculin if a reaction occurred, it need subject the patient to no risk. It should be worked up very gradually through the course of weeks and months to as much as three hours on a stretch of walking or eighteen holes of golf. This brings the patient to the end of his cure fit and strong rather than fat, with a weight not over or even slightly under his insurance standard, full of healthy vigor, not afraid of himself, knowing how much he can do and what he cannot do, and ready to resume his work with a chastened knowledge of his former hygienic sins and a confidence that in the future he will know how to combine health with work.

And how shall we safely gauge the use of rest and exercise? First, it is essential that the doctor keep a close tab on his patient's life, at first biweekly, then weekly, and never less than once in two weeks, so as to detect and remove over-exertion.

Temperature.—Of our guides, temperature is the first and best. Every patient, whether febrile or not, should, when first beginning treatment, go through a period of absolute rest not merely for its therapeutic effect, but that we may become familiar with his normal run of temperature. If we find after a few days a normal temperature, and if the other data are favorable, we can allow him up, and give him increasing graduated walks, to be measured carefully by the watch. If the temperature in the afternoon is as high as 99.4° he can be gotten up at first in the morning only, then in the afternoon as well, and finally all day, the graduated walks coming a little later when he has proved that his trouble is inactive enough not to show a fever rise after talking, reading, or visitors. If it is 99.6° to 100.6°, bed rest, while not absolutely essential, is best till it gets and keeps the temperature down as it usually does, but if the patient is of a restless, fretful, high-strung temperament it is often wise to allow an hour or so in the morning in a reclining chair. If the temperature is 100.6 or over, absolute bed rest is necessary, though I cannot agree with those extremists who insist on the use of the bed pan and the urinal and absolute recumbency without motion, for I think, for psychological reasons, this is undesirable. In cases where persistent bed rest fails to reduce temperature, and yet where the general condition is fair or good, I, at times, experiment with getting the patient up, and occasionally find that the temperature will thereupon disappear. It is scarcely necessary to note that the doctor must be sure that the patient is not running a concealed night temperature. During bed rest it is most important to keep the patient heartened up and to teach him mental relaxation and resignation, for many patients who are at physical rest in bed are in a constant mental turmoil, and kicking against the pricks, which is as bad, or worse, for them than physical exertion.

Pulse.—Unduly rapid pulse (100 or over) is a good indication for rest, but when on experiment we find that moderate exercise causes no rise, it need not be an absolute indication for rest, but only for the reclining chair. Further, some people run constitutionally fast pulses, and if we can be sure of this it can be discounted.

Cough and Expectoration.—Abundant cough and expectoration are made worse by talking, laughing, and walking, but such cases are apt to be febrile, so we do not need this as a guide. Blood streaked or pink expectoration is an absolute contraindication, but I have seen patients in whom such blood streaking was apparently a permanent habit, even when they were febrile and doing well, and after long tests I have, with great benefit, allowed walking in such cases.

Weight.—Any patient who is losing weight, save unduly fat ones, where we wish to allow a slow and cautious reduction, must be at chair rest, or at times bed rest. A poor weight, however, is not necessarily a contraindication in a patient who is normally spare but is wiry. In considering weight, I find it of great value to record not merely the patient's average weight, but his average best weight, his absolute best, and his insurance standard as gotten from the tables, and I like to keep the latter before me as my ideal for him; and I consider it unfortunate for him to surpass that ideal very much, a really fat patient not being a good result of our treatment.

Fatigue is one of our best guides. A little healthy tire, passing off rapidly, has no significance, but to get really tired or fagged is bad, whatever the temperature or pulse may be. However, if the patient's exercise is increased by a little each day, this can be entirely avoided, save as an indication of an intercurrent congestion.

Mental Attitude.—A patient who has been treated by prolonged bed rest is usually much afraid of any exercise, and has to be brought to it very gradually, for to make him do what he considers dangerous is unwise; but since the proof of the pudding is in the eating, he will soon be converted if he finds the one, two, or three minutes have no bad effects. Of course, mental rest is much more difficult to obtain than physical. A patient may be lying quiet in bed, and yet, unknown to us, may be worrying or suffering, and fearing terrible things. This is difficult to find out. Yet, if we are to help our patients, it is up to us to discover

it, and it is at this point that the phthisiotherapeutist must take on the character of the kind and sympathetic, but firm, father confessor, in order that the patient may practise with him that mental catharsis which alone can put his mind at rest. Indeed, so essential is mental rest that we should never be satisfied until we have secured it for our patients, if possible.

Methods of Exercise.—In the bed patient, it may, though very seldom, be necessary to give artificial exercise in the form of abdominal or limb massage (never chest) to keep his digestion going and to burn up waste products. The first step toward exercise is in sitting in a reclining chair for half an hour, the time to be lengthened each day, two-thirds of it spent recumbent, one-third erect, and for this a proper chair, which will lie back flat, or come straight up by the motion of the patient's body, is essential; and such a chair must have an absolutely flat back, to encourage erect shoulders, which I believe to be most important for the tuberculous patient. For the patient who has to be constantly recumbent there is nothing better than the Adirondack recliner, but when he reaches the stage of sitting up he cannot let down his legs, and, its adjustment not being automatic, it discourages frequent change of position, which is important to prevent tiring of a single set of muscles and to prevent fatigue or monotony. In this case, the Bloch chair is much better. The next step in exercise is crocheting for women, solitaire for the men, and reading for both of them, but any of these can raise temperature if overdone. Next comes walking, according to the rules already noted. To my mind, no other exercise can compare with it, and it can be perfectly graduated from the very shortest, quiet stroll to a brisk morning's walk uphill and down dale, as indicated. Driving is not as passive and easy for patients as short walks, and no one drives for less than fifteen minutes or half an hour. Moreover, the temptation to overdo is much greater, and the patient does not have the natural warning of his overdoing. Autos are easier than carriages, but I allow neither one or the other until the patient can walk from one-half to an hour without bad effect. When a patient has been afebrile for a long time, when the process is inactive, with no moisture and little or no expectoration, I allow, in selected cases, short rides on a racking or pacing, but never a trotting horse. This is especially good for dyspeptics, and can be worked up by degrees from one to two hours. To those of limited means, trolley riding is enjoyable, and it can be allowed sooner than carriage driving, if the trolley is near the house. After the patient can walk easily for an hour on the level, I have him begin the ascent of increasingly steep hills until the rather steep hills in Asheville can be easily taken, and I am never fully satisfied with the patient, on discharge, if he is unable to walk three hours over our hills with no undue dysconea, with no loss of weight, fatigue or tachycardia. This is the nearest I can come to a test of his ability to stand the tax of his work, and his ability to do this easily shows me that his physical force is reestablished and that he should have such vitality as to enable him to complete the fibrosis of his case and to resume a normal life. What a difference between such a patient, rosy, strong, with firm muscles and bright eyes, with full knowledge of the possible dangers of relapse, yet also with the knowledge of how to prevent it, and, on the other hand, the fat, puffy, timid one, just up from his couch, afraid to make any exertion, and prizing each pudgy pound of fat, which, if he but knew it, represents a burden rather than an asset.

After all, we are not trying merely to save our patients' lives but to return them to normal, useful activity so strengthened that they can reasonably be expected to stand its strain, and so instructed that they will take the happy mean between a timid anxiety lest they relapse and that foolhardy overdoing, and return to old indiscretions, which is so sure to land them into trouble.

Aside from the physical advantages of handling our cases with a less unreasonable fear of exercise, are its manifest psychic advantages. It breeds courage instead of timidity, hope instead of fear, and thus it makes the mental attitude much more favorable for getting a good result. We doctors are too apt to treat our patients' bodies and not their minds, but every patient that leaves the cure must not only be physically rebuilt; he needs, with rare exceptions, to be mentally rebuilt, to be a better man, with more will power, with more knowledge, with more determination, with more self-mastery than he had before, and in the mental education which leads to this I believe that a less timid use of exercise can play a large part.

61 French Broad Avenue.

HISTOPATHOLOGICAL CHANGES IN FIVE CASES OF MYELITIS.

By G. B. Hassin, M.D.,

Chicago.

Attending Neurologist, Cook County Hospital.

(From the pathological laboratory of Cook County Hospital, Chicago.)

That the histopathological changes in various organic nerve lesions are not confined merely to the nerve structures, but are also to be found in the neuroglia tissue, is a fact established principally by the late Alzheimer and his pupils. Indeed, the pathological findings in the glia so far are even of a greater variety and interest than those furnished by the nerve tissue proper. It is, therefore, of great importance to follow up the possible changes in the glia, as well as in the nerve elements, in each organic nerve lesion and point out their characteristic features.

As I have had the opportunity to study five cases of myelitis, three of which were due to Pott's disease, I wish to give a brief outline of my findings, as they pertain principally to the changes in the glia.

Case I.—Woman, 31 years old, entered Cook County Hospital April 17, 1915, with a spastic paraplegia of eight months duration. The paraplegia was associated with a total anesthesia of the lower half of the body, incontinence of the bladder and rectum, exaggerated tendon reflexes in the lower limbs, bilateral patellar and foot clonuses, positive Babinski and Oppenheim, and a positive so called "defense" reflex, *i.e.* flexion of the toes (down) caused various spontaneous movements of flexion—extension of the paralyzed lower limbs. The abdominal reflex was absent. The anesthesia reached the umbilicus in the form of a circular line around the body, and three weeks later it was found at the level of the nipples. At the same level a kyphosis was present. A Roentgen examination showed a large abscess in the region of D 3—8 vertebræ and a post mortem, done May 23, 1915, the day following the patient's death, revealed an abscess in the above area, projecting anteriorly into the chest cavity. The sack of the abscess was thick filled with cheesy yellow tuberculous pus. The bodies of the vertebræ, at this level, were eroded, and the cord compressed, in fact was almost

totally severed, and hardly any substance suitable for sections was here left. The meninges, at this level, showed no infiltration, which was very pronounced in the lowest portions of the spinal cord and around the cauda equina. The gross examination of the spinal cord showed, at the level of 5th and 6th dorsal verte-

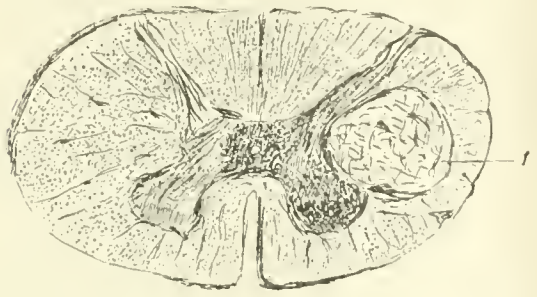

Fig. 1.—Patch of softening in the lateral column, at *f*.

bræ, a triangular cavity, protruding into the posterior columns and the posterior horns. In other places, below, instead of a cavity a round or oval patch of softening could be detected occupying the same place, but in other sections it occupied the lateral columns between the posterior and anterior horns (Fig. 1). In other places the spinal cord appeared collapsed and disfigured. Thus, on Fig. 2 the upper portion of the spinal cord can be seen turned toward the right in the form of an arch ending in a patch of gray matter consisting of Rolando's substance and remnants of gray matter. A part of the latter is to be found also back of the central canal. Such changes are known as heterotopic changes, and are considered as artefacts, due to the handling of the spinal cord which in this case was extremely soft, resembling a thick milky fluid.

The microscopical examination showed, above and below the destroyed areas, the usual picture of ascending and descending degenerations, which were studied along with the patches of softening with various methods: Weigert-Pal, Mallory's anilin-blue, Mann, Bielschowsky, Marchi, Herxheimer, Nissl and combined Marchi-Mallory methods.

Fig. 2.—Heterotopic changes in the spinal cord.

On Mallory anilin-blue and Mann methyl-blue—eosin specimens the degenerated and healthy zones showed preserved medullated axones, but in many places the myelin appeared in the form of yellowish patches or leaves. Many portions of axones therefore were totally uncovered, and the visual field appeared dotted with numerous yellow patches of myelin scattered amidst blue axones.

In the diseased areas, some of the latter were somewhat swollen, spindle shaped, and on anilin-blue specimens counter-stained with osmic acid, they clearly showed the crossings of Ranvier around which the myelin patches were especially numerous.

Chromed sections counterstained with anilin-blue revealed quite numerous blue granules scattered all along the axones and the neighboring glia tissue. These granules are evidently what Alzheimer described as "methyl blue granula" (Fig. 3). The glia fibers were very thin, forming delicate meshes studded with numerous glia cells and amyloid bodies. The characteristic feature of the spinal cord changes of the regions not *directly* involved in the softening, were almost total absence of reactive activity on the part of the glia, the presence of patches of myelin with relatively good condition of the axones and the presence of methyl blue granula.

The microscopical examination of the *patches* themselves shows them surrounded by a wall of glia fibers

Fig. 3.—*mg*, methyl blue granules, *ax*, axone; *myel*, myelin globules.

and consisting of enormous amount of fragments of axones and myelin. Some of the broken axones are tortuous, swollen, thickened, but are not surrounded by glia. The latter shows the usual network of somewhat thickened and proliferated fibers and protoplasma poor glia cells, containing nuclei with numerous dots within ("caryolysis"). Occasionally, but very rare, so-called granular bodies ("Gitterzellen") could be seen within. In general, the patch impresses one as an orderless mass of débris of broken up axones and myelin scattered among the meshes of glia tissue which does not show the reactive changes as observed in cases of secondary degeneration. Neither Marchi nor Herxheimer scarlet red stains show the presence of fat in the patches. It is an established fact that when a nerve fibre is damaged, *i. e.* is broken up in smaller fragments, the gila quite early (during the first few days according to Jacob) begins to manifest various reactive changes of proliferative nature. Thus, the glia cells are transformed into complicated structures—myeloclasts, myelophags—which break up the scattered débris into smaller particles and transform them in lipoid substances which, in their turn, are picked up by other gliogenous cells, the so-called granular, honeycombed, bodies ("Gitterzellen" of various types) and thus finally removed to the blood vessels. The field is then cleared away from the damaged tissue, is as the German authors say, "abgeräumt."

As it can be seen, in this case the damaged nerve tissue, the débris of axones and myelin were not removed, were not buried, as it were, because there were no signs of activity shown by the glia tissue. The latter was evidently rendered by some pathological process as helpless as the nerve tissue itself, and we must assume that the pathological condition of the spinal cord was that of partial necrosis or softening, also known as *myelomalacia*.

In myelomalacia we thus find *lack of reactive activity* on the part of the glia, in the presence of broken up fragments of nerve tissue. Somewhat of a different character are the pathological changes as found in another case of Pott's disease.

Case II.—Man, 22 years old, entered Cook County Hospital June 5, 1915, with a paraplegia which rapidly developed within the last two weeks. He became totally helpless during the last ten days. About eight months previously he fell on his back, but was not confined to bed. The previous and family histories were good.

Examination. The patient is extremely pale and emaciated with normal mentality and normal cerebral nerves. In the left supraclavicular space, and just in front of the left trapezius muscle there was a soft, painless mass, the size of a hen's egg, freely movable. It appeared five days before the patient became paralyzed. A similar mass was present in the left pectoralis major near its origin, extending from the 2d to the 5th rib. Below this mass there was another swelling the size of a half dollar. The puncture showed the presence

of pus which was removed, but the mass filled up again. The neurological examination showed a complete spastic paraplegia with increased tendon reflexes, positive Babinski, Oppenheim, and a bilateral patellar clonus. The defense reflex was very marked, but the abdominal and the cremasteric reflexes were absent. There was incontinence of bladder and rectum. The paralysis was associated with complete anesthesia up to the navel, while from the latter up to the ensiform process the pin pricks were perceived as "finger touch." A couple of weeks later, the anesthesia reached the level of the fourth rib. The Roentgen examination done repeatedly proved negative. The luetin, Wassermann in sp. fluid were negative (blood gave a positive Wassermann). In the further course of the disease, bed sores rapidly developed, and the patient died December 12, 1915.

The post mortem was performed four days later and among other findings, it revealed diffuse tuberculous masses in the lungs, a large tuberculous abscess over the 5th and 6th dorsal vertebræ and an extensive peripachymeningitis over the dorsal and lumbar regions. Nowhere was the spinal cord compressed or disfigured as in the Case I. Weigert-Pal stain showed marked ascending degeneration especially in Goll columns and a descending degeneration in the pyramidal tracts. In addition, there was a "patch" of softening involving one of the posterior horns and a portion of the posterior columns in the lower cervical region.

Longitudinal and transverse sections of various portions of the spinal cord were studied on frozen, celloidin and paraffin sections with the staining methods of Mann, Mallory's anilin-blue, Herxheimer, Weigert-Pal and Alzheimer's Lichtgrün-Acid Fuchsin.

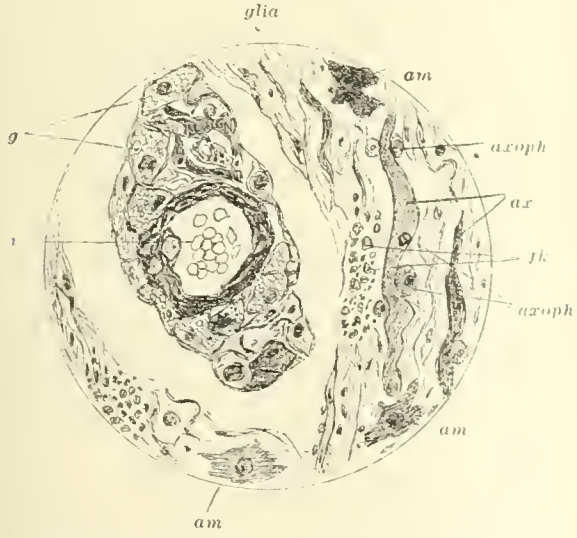

FIG. 4.—*am*, Ameboid glia cells; *axoph*, axophags; *ax*, axone; *v*, blood-vessel with granular bodies (*g*) in the advential space; *fk*, füllkörperchen.

The patch contained enormously swollen axones (Fig. 4), pale and homogeneous in appearance, bluish in color. Occasionally there could be found axones unusually thin and densely red. Some of the axones showed excavations (Fig. 4) filled with glia cells, so-called axophags first described by Buchholz in a case of myelitis in 1899.[2] Everywhere there were scattered, in large quantities, granular bodies which on scarlet red specimens stained according to Herxheimer showed the presence of fat. No glia cells or glia fibers could be detected, these having been replaced by pale homogeneous protoplasma rich cell bodies with a densely stained, so-called pycnotic, and eccentrically located nucleus—ameboid glia cells (Fig. 4, *am*). In other places the glia tissue was replaced by small round or quadrangular in shape bodies described by Alzheimer as "Füllkörperchen (Filling bodies) Fig. 4. The same ameboid glia and Füllkörperchen were in evidence in the degenerated columns of Goll and the pyramidal tracts which were packed with the above-mentioned granular bodies.

The striking feature, in every specimen, was the so-called ameboid transformation of the glia tissue, in the form of the ameboid cells and Füllkörperchen. On Lichtgrün-fuchsin specimens numerous red, dust-like granules covered the ameboid glia, so-called fuchsiophile granules of Alzheimer.

The patch thus shows in this case findings entirely different from those in the previous case. We do not see here the broken up fragments of nerve tissue helplessly scattered among the meshes of glia fibers as if waiting to be removed, but we find here lipoid substances enclosed within numerous granular bodies, so-called "Gittezellen." Instead of neuroglia tissue we find ameboid glia cells and Füllbodies of Alzheimer, both these elements actually dominating the histopathological picture. In this case the broken up or damaged nerve elements evidently were already transformed into lipoid substances and partly removed. Accordingly we see here along with signs of primary nerve degeneration those of secondary degeneration, both being in evidence on the same specimen. The secondary degeneration is represented by vacuoles, which contain fragments of axones, myelin or gliogenous formation described by A. Jacob as myeloclasts, myelophags, while the primary degeneration is represented by swollen and excavated axones, axophags, and lack of glia proliferation. The glia, as I said, was here universally replaced by ameboid glia and Füll-bodies, which types being entirely foreign to typical secondary degeneration were present on every specimen of the gray and white matter. We can therefore speak of universal ameboid transformation of the glia in this case, as it was present in every portion of the spinal cord even where the axones and myeline were undamaged.

The biological significance of the ameboid glia is, according to Alzheimer,[3] to help "liquefying" the damaged nerve tissue and thus to clean up the latter from various catabolic products, the so-called "Abbaustoffe." The ameboid glia does not produce fibers, and it is not certain whether it picks up broken up nerve tissue. At any rate, the presence of ameboid glia indicates, according to Alzheimer, a profound, far-gone destruction of nerve elements, a possible serious infection or intoxication. Therefore, Case II, with its universal ameboid transformation of glia, must be considered of much more serious character than Case I, where no ameboid glia was present and where the clinical symptoms and the course were as compared with Case II considerably milder in character.

CASE III.—The pathological findings varied again in the third case, a woman, 35 years of age, who entered Cook County Hospital July 26, 1915, with complete paraplegia which she stated existed for fifteen days. About two years previously her spine was badly jarred from a fall, for which she has been treated for 18 months in a hospital (had a cast). Six years previously she had pleurisy. The examination showed an emaciation, kyphosis in the upper dorsal and lumbar regions and some râles in the base of the lungs. The lower limbs were totally paralyzed, but as in the previous two cases the so-called defense reflex was present. The paraplegia was spastic, with exaggerated tendon reflexes, Babinski, Oppenheim, and total anesthesia up to the level of the fifth dorsal vertebra, combined with complete paralysis of the bladder and rectum.

The Roentgen examination revealed a marked bone degeneration of the 4th, 5th, 6th and 7th dorsal vertebræ which showed signs of caries and collapsed bodies. The 12th dorsal and the first lumbar vertebræ also were extensively involved.

Enormous bed sores developed and the patient died December 14, 1915, after two years of illness.

The post mortem revealed among other findings an extensive peripachymeningitis covering the D 3-5, the entire lumbar region and the cauda equina; caseous tuberculosis of D 3-12 and L 1-3 vertebræ; marked compression of the spinal cord adjacent to D 3-5; a slight encapsulated nodular right apical tuberculosis, tuberculous abscess (bilateral) of the psoas muscles and necrosis of the D 2-4 vertebræ bodies.

The spinal cord appeared microscopically perfectly normal on transverse sections, but the microscopical examination studied with various methods, mostly on

frozen sections, revealed all over the spinal cord a typical picture of myelitis. On every section the so-called Swiss cheese appearance of the spinal cord was clearly seen, the fields of vision having been everywhere covered with numerous vacuoles. A great many of these were empty, *i. e.* without any contents, but some contained remnants of axones and myelin surrounded by normal or modified glia tissue. The changes in the axones themselves were confined to their tumefaction which, however, was not so pronounced as in the previous case, but as in the latter the most interesting changes were found in the glia. The marginal glia, the white and the gray matter showed presence of numerous ameboid glia cells, frequently in a condition of so called *cystic* degeneration, or in the form of minute granules. Numerous minute blue granula were scattered all over the grey and white matter, so-called methyl blue granula (on Mann specimens). Füll-bodies, so numerous in the previous case, were here scant, but the granular bodies, the so-called γ variety of "Gitterzellen" were present in large amounts. On Herxheimer specimens they showed enormous quantities of larg drops of fat. The vessel walls showed infiltration with lymphocytes. In some areas the microscopical picture was that of typical secondary degeneration which, at the first glance, very much resembled that in amyotrophic lateral sclerosis, but differed from the latter by the presence of the ameboid glia which is foreign to amyotrophic lateral sclerosis.[4]

The typical picture of myelitis, combined with that of pronounced secondary degeneration, is the characteristic feature of this third case, contrary to the focal necrosis and the pronounced phenomena of primary nerve degeneration found in Case II.

Before we proceed with the discussion of the variety of the microscopical findings in these three clinically similar cases I wish to briefly mention the findings in two other cases apparently of different etiology.

Case IV.—Mrs. J., 36 years old, married, with a good previous and family history, entered the Cook County Hospital August 13, 1915, with a spastic paraplegia. The latter existed for about ten months and developed gradually during the previous six months after a severe fall on her back. At the time of her admission to the hospital she has been complaining of severe, sharp, cutting pain in the limbs, in the back and a tingling sensation in the left forearm.

Examination showed a well-nourished white woman lying with the thighs flexed on the abdomen, and the legs on the thighs. Any voluntary movements in the lower limbs were impossible and the passive greatly restricted. Thus the right leg, by using great force, could be straightened almost in full, while the left leg, even with a considerable effort used, could be extended but to a limited extent. The upper limbs were normal in every respect. The abdomen showed a marked rigidity on the left side where a hard mass, somewhat nodular in shape and enlongated, was felt rising from the pelvis up to the level of the costal margin (rigid muscles). The abdominal reflex was absent, the tendon—patellar and Achilles—greatly exaggerated, with a right ankle clonus, positive Babinski and Oppenheim. Patellar clonus could not be obtained on either side. Flexion of the toes caused flexion-extension movements in both lower limbs ("defense reflex"). Sensibility examination revealed anesthesia for pain up to the seventh rib, and a marked hyperesthesia up to the second. The temperature senses (heat and cold) were lost up to the second rib. The muscle sense was present. The bladder and rectum—paralyzed. The spinal fluid was under the increased pressure, gave a positive Wassermann, positive Ross Jones and Noguchi and 30 lymphocytes per cubic millimeter. A Roentgen examination by Dr. E. S. Blaine revealed a shadow of increased density on the left side of the seventh cervical vertebra covering the transverse process. The latter was seen to be complete, however."

Syphilis was denied, and there was but one pregnancy that ended on the third month in a spontaneous abortion.

The patient suffered greatly from pain in the rigid abdomen that resembled a tumor, and from the involuntary discharges.

Mercury inunctions and potassium iodide given for a month were without effect.

The history and the *x*-ray findings suggested an extradural lesion which was interpreted as a possible tumor, or bone changes caused by the fall, but which was shown by the post-mortem to be a hypertrophic pachymeningitis of the upper dorsal region. An exploratory laminectomy was suggested which the patient readily consented to. It was done on November 27, 1915, by Dr. Morf in the region of the third, fourth and fifth dorsal vertebræ. The dura was slit for two inches in the mid line, but no tumor was found. The patient made a nice post-operative recovery and a month later she was transferred back to the neurological service in practically the same condition as before the operation. The anesthesia was found almost complete up to the level of the fourth rib.

In the further course of the disease, the patient developed a cystitis, bedsores in the lower limbs, and a hypostatic pneumonia to which she succumbed March 14, 1916.

The post mortem done within the first 24 hours showed numerous calcified, bony plaques all along the posterior portion of the pia, and an enormusly thickened dura in the region of the seventh cervical segment stretching down to the middle dorsal region. The thickening was ½ inch in width and comprised the posterior and lateral surfaces of the spinal cord, but was more pronounced in the posterior portion. The spial cord was greatly reduced in size in the region corresponding to the thickened membrane.

There were customary changes of secondary degeneration found in the cervical and lower dorsal as well as in the lumbar regions, while in the upper dorsal, corresponding to the area of the thickened dura, there were changes of a different character. A very small patch of softening was present near the posterior commissure, in the posterior columns involving but one segment (approximately the fourth dorsal), and the microscopical examination on frozen sections stained with Mallory's anilin blue, Mann's methyl blue-eosin, Bielschowsky and Herxheimer's scarlet red gave findings as follows: Numerous well retained axones surrounded by an undamaged myelin sheath; many of the axones were tumefied, tortuous, with knobby thickenings, and frequently broken up in small fragments enclosed within vacuoles. Numerous so-called Marchi globules ("Marchi-Schollen") situated in long rows were present in the places of former axones.

More interesting were the findings in the glia, where a great number of protoplasma rich glia cells could be seen, but where the glia fibers were frequently replaced by so-called Füll-bodies of Alzheimer.

These Füll-bodies entirely filled, on some sections, the spaces between the nerve fibers, and were distinctly seen on every specimen stained with Mallory's anilin blue, Mann and Bielschowsky's silver nitrate method.

On the latter specimens, the visual field was totally covered with these bodies among which solitary well-preserved axones could be seen running. Ameboid glia cells were also frequently found, of large size and occasionally cystic in appearance, but surrounded by the Füll-bodies. Other glia cells showed in the form of myeloclasts, myelophags and various forms of granular bodies, so-called "Gitterzellen," principally of α and γ varieties. These granular bodies were surrounded by Füll-bodies, but not by glia fibers as in amyotrophic lateral sclerosis, though in less damaged areas glia fibers could be distinctly seen.

The most characteristic feature was the ameboid transformation of the glia which is almost pathognomonic for the various forms of degeneration to be found in myelitis. The silver-nitrate specimens stained according to Bielschowsky show, with the low power, numerous islands resembling those in the degenerated posterior columns of tabes.[5] However, with the high power, the islands appear in myelitis consisting of a mass of Füll-bodies among which run solitary axones, which in tabes, at least on my specimens, are surrounded not by Füll-bodies, but a mass of delicate glia fibers.

Outside the foci, in the dorsal region, for instance, the spinal cord shows completely preserved axones, but profound changes in the glia—its ameboid transformation. The transverse sections of such areas, not damaged by the myelitis, shows a network of ameboid glia that everywhere surrounded the *normal* nerve fibers. The vessel walls, the adventitial spaces, were infiltrated with numerous granular bodies and surrounded by Füll-bodies, while in the posterior columns numerous methyl blue granules could be seen.

The microscopical picture thus showed a localized myelitis with combined involvement of the neuroglia

and nerve elements. The peculiar features were, in this case, the widespread neuroglia changes even where the nerve fibers were well preserved, and the etiology, in the form of a pachymeningitis. Whether the latter caused the myelitis by edema or direct pressure or toxins I will not discuss this question, but will point out the relatively mild findings in the nerve fibers as compared with those in the glia. That this case was not a tuberculous myelitis is proven by the absence of any primary foci anywhere in the body and by the absence of peripachymeningitis which was so pronounced in the previous three cases. Yet in this case the pathological picture of myelitis, though less severe, was somewhat resembling that in the previous three cases with a different etiology. In Case V we have the most interesting clinical as well as the histopathological findings.

Case V.—Man, 31 years of age, cook by occupation, entered the Cook County Hospital with a flaccid paraplegia, retention of urine, and feces and anesthesia up to the inguinal region on both sides. The paralysis set in suddenly three days before he entered the hospital, preceded by a burning sensation all over the body and retention of urine which lasted for two days previous to the paralysis. Five days previous he contracted a gonorrhea. Fifteen years ago had a chancre. The patient was married, but had no children. His wife had one miscarriage.

Examination showed a well-nourished male, with normal mentality, normal pupillary reaction and normal cranial n.n., normal heart and lungs. The abdomen was greatly distended, tympanitic, no tenderness, no tumor. Inguinal glands palpable. A purulent discharge containing gonococci from the urethra. The lower limbs were in a condition of flaccid paralysis with complete loss of the tendon reflexes, absence of Babinski and Oppenheim, loss of abdominal and cremasteric reflexes. Marked anesthesia up to the inguinal region, and hypoesthesia up to the level, midway between the umbilicus and ensiform process. The patient suffered much from persistent vomiting, great abdominal distention and labored breathing. The condition grew worse and the patient died March 15, 1916, one week after he entered the hospital, and ten days after the onset of the paralysis. A diagnosis of lumbar myelitis was made, probably of gonococcus origin. Wassermann in the spinal fluid was positive, Nonne and Noguchi also positive. Lymphocytes in the spinal fluid showed 30 cells per c.mm. The post mortem showed a diffuse myelitis of the entire lower half of the spinal cord and a large focus of softening in the lumbodorsal region. The lumbar enlargement of the spinal cord was the seat of a large softening, one inch long, occupying the posterior half of the spinal cord. The adjoining dura showed no changes. In the lower dorsal region another focus of softening was present. In the remaining portions of dorsal region of the spinal cord a diffuse infiltration was noticed, obscuring the distinction between the white and gray matter.

Transverse and longitudinal sections from various levels were stained with Nissl, Mallory, Mann, S-fuchsin-lichtgrün, Mallory's hæmatoxylin and Herxheimer.

The most interesting findings were in the glia, which in some places (in lumbar region, for instance) was totally replaced by ameboid glia and Füll-bodies which could be found even in the normal areas. The ameboid glia cells were unsually large, excavated, eaten away, as it were, the excavations having been filled with glia cells. In other places the ameboid cells appeared cystic, in the presence of a large number of unchanged proliferated, glia cells. The blood vessels were unusually proliferated, hyperemic, their lumen often restricted, the adventitial spaces—packed with a large amount of lmyphocytes (Fig. 4) and granular bodies filled with fat (Herxheimer scarlet red stain). The gray matter, especially the posterior postions in the damaged areas, was rich in Füll-bodies, ameboid glia, and methyl blue bodies, the changes in the ganglion cells and axones having been not very pronounced.

The areas, not directly involved, as the upper dorsal and cervical regions, also showed glia changes, in the form of ameboid glia. The anterior, the lateral columns which practically contained normal fibers showed ameboid transformation of the glia. Some of the ameboid cells were cystic, granular, containing a shrunken nucleus eccentrically located. Füll-bodies in the undamaged areas were exceptional.

As this case was posted on the fifth day after death, there were, as in Case II, numerous changes present due to post-mortem changes as described by Rosenthal,[6] especially on lichtgrün-fuchsin specimens. I will not touch upon these findings which I shall report in full some time in the future.

The glia changes in this case were of much graver character than in any of the previous four cases—they were more pronounced and more widespread. The question arises whether the severity of the clinical symptoms, of their course, reflects in any way upon the condition of the glia, or vice versa, whether the degree of glia changes can give any idea of the seriousness of the nerve lesions. This problem was studied experimentally by F. Lotmar[7] on rabbits, in which he produced myelitis and encephalitis by injecting the dysenteric virus either in the form of sterile agar cultures of *B. dysenteriæ* or in that of a solution of toxins. The injected animals were left alive from fifteen to twenty-one days, some having succumbed to the infection, some having been killed by bleeding. Of fifty-five animals thus experimented upon twenty-four were killed and showed pathological changes in the central nervous system, which changes he divides in two types. To type I he refers those cases of acute myelitis, where the degeneration of the nerve fibers was associated with the ameboid transformation of the glia; to type II he refers cases in which the destruction of nerve tissue was combined with glia changes of progressive or proliferative character. Lotmar found a clinical and pathological difference in both these types. The pathological features in type I were hemorrhages in the tissues and around the vessels, exudation of fibrin, of polynuclear leucocytes, thrombosis of the vessels, degeneration and vacuolization of the ganglion cells, swelling of the axis-cylinders and ameboid transformation of the glia with changes of the marginal glia in the form of so-called glia reticulum. The glia in this type of myelitis lacks reactive activity. It does not and cannot replace the defects caused by the dying or dead nerve tissue.

In type II the glia, on the contrary, shows remarkable activity and replaces the damaged nerve elements, the vessels, the endothelium and the adventitial elements proliferate. The glia is in this type stimulated, forms numerous granular bodies rich in lipoid substances, while in type I the glia is insufficient, is unable to replace the dead nerve tissue, and thus must necessarily reflect upon the clinical picture. Indeed, in myelitis type I the animals live a very short life, only one rabbit could be kept alive for seven days, while with type II the animals could be kept alive up to twenty-one days, and then their life was cut short artificially.

The course was very mild in type II, the paralysis and other clinical phenomena having disappeared at the time of death, while in type I the symptoms showed no retrogressive signs. The prognosis was, therefore, bad in type I and comparatively good in type II. Such pathological and clinical manifestations much depended upon the dose injected and also upon the individual resistance of each animal. Small doses of the dysenteric toxin usually caused the milder type II, the large doses, type I, while medium doses would cause either type or a mixed type, depending upon the individual resistance. In the mixed type lesions peculiar for either type may obtain or in the same focus of myelitis lesions of

both types may be present. The reason why type I gives a bad prognosis Lotmar sees in the fact that the ameboid glia, though able to retain *in loco* the products of the broken up nerve tissue, cannot transform them into lipoid substances, which process is accomplished by the mesodermal elements of the blood vessel walls. Therefore, this type of myelitis is rich in so-called *prelipoid* substances which are not yet converted in fat and which on suitable specimens show as various granula—fuchsinophile, lichtgrün, methyl-blue granula, etc. In type II a powerful glia proliferation takes place with enormous production of fat into which the dead or broken up nerve tissue is transformed and thus rendered harmless, which is not the case in type I. In the latter the glia is "insufficient," and cannot transform the products of plasma desintegration into lipoid substances. These products may thus reach the blood and create a general danger for the entire body. Such an occurrence is impossible in the type II, where the glia is "sufficient," producing granular bodies, which retain the dangerous products until rendered harmless.

F. Lotmar's instructive conclusions were arrived at from experiments on animals. It was, therefore, interesting and even imperative to determine whether human pathology ofiers any facts similar to those established by F. Lotmar. In the five cases of myelitis I studied with the same methods used by Lotmar the pathological findings as I showed somewhat varied in each case, but one feature was common, namely, the ameboid transformation of the glia, which was very pronounced in four cases out of five. In one case (Case I) the dead focus was sequestered and walled off from the rest of the tissues, and no ameboid glia could be demonstrated in this case, while in two cases (II and V) with especially severe and rapid course the ameboid changes were equally severe. Yet in both these cases the pathological findings were different from those in Lotmar's experiments, *i.e.* in none of my cases was type I of Lotmar present, but always combined with type II. In other words, the mixed type of myelitis, as given by Lotmar, was the characteristic feature in every case where the ameboid transformation of the glia was pronounced. This was very severe in the cases II and V, which also clinically showed a rapid malignant course (Case V) and a profound general intoxication (Case II). The clinical facts are thus in complete accord with the serious pathological changes of the glia. The condition of the latter may probably indicate the extent of the lesion of the nerve tissue, the extent of intoxication or infection or, as Alzheimer puts it, "the more the neuroglia resembles the ameboid type the more profound are the pathological changes in the central nervous system which changes may, to a certain extent, be measured by the degree of the ameboid glia formation."

BRAIN-TUMOR OR HYSTERIA.

By J. VICTOR HABERMAN, A.B., M.D., D.M.S. (Berlin).

New York.

Instructor in Clinical Psychology and Psychotherapy, College of Physicians and Surgeons, Columbia University; Attending Physician in Neurology, Vanderbilt Clinic, New York.

THE following case is one of peculiar interest from the point of view of diagnosis—and the frailty of diagnoses—and of considerable importance in elucidation of the difficulty that may at times arise in differentiating an hysterically patterned clinical picture from one actually and pathologically occasioned. This history also points to discrepancies in hospital observations, difficult to explain.

The patient, L. R., 31 years of age, was first seen by me at Roosevelt Hospital in mid-September, 1913. The history given by the patient at that time was that she *suddenly* became sick in March, having been entirely well previous to this, and after trying home treatment, or no treatment at all, for a few months, and not improving, finally went to the —— Hospital. The symptoms complained of throughout these months and because of which she finally applied for admission to the latter hospital, were: continuous vomiting, headaches, buzzing in the head, dizziness, "spots before the eyes," and great weakness of the right hand and foot, "almost paralysis," as the patient put it. Vision of the right eye seemed entirely gone. She remained several weeks under observation at this hospital, where brain tumor was diagnosed and operation advised. The patient refused operation and left the hospital. A little while after she applied for admission to Roosevelt.

On inquiry it was learned that the patient's urine on her admission to the ——— Hospital contained abundant albumin and casts, that the fundi showed changes, and that her vomiting had been projectile. Nephritis in addition to the brain tumor had been thought of.

At Roosevelt, our patient gave in addition to the above, the history of having vomited blood on three occasions, 7, 3, and 1 week before admission (which no doubt came from her throat, which was severely congested—from constant vomiting and coughing), that she had frequent choking sensations, frequent attacks of hoarseness, and that she often saw double.

On my visit I made the following anamnestic notes: Her parents and grandparents appeared to be normal individuals. There were neither alcoholism, psychoses, epilepsy, hysteria, nervous disease, nor eccentricities in the ascendants. Six children of these parents, however, were *very* nervous, two of them being sleep-walkers and another having varied fears. A cousin of the patient is insane.

Infancy was normal save for convulsions "from teething." She walked and talked at the proper age. As a child she had measles, scarlet fever, and pneumonia, and recovered from each without residuals. She did not have chorea, strange spells of any kind, somnambulism, enuresis, nor headaches. But from the age of six on she would occasionally get hoarse without apparent cause, off and on, even up to the present. Convulsions.* which "began early," continued "once in a while" up to her eighth year (never thereafter). No reason could be given for the convulsions, which, the patient assured me were not accompanied by tongue bite, enuresis, or injury.

During adolescence some stomach trouble occurred (nature and cause not known). She bore two healthy children. There were no miscarriages. She never took intoxicants nor drugs nor came in contact with any metal poisons, nor experienced a shock at any time, either physical or psychic. Bowels have been regular.

*These were not the same "teething" convulsions which occurred in his infancy.

Menses regular up to three months ago, then became irregular. She occasionally finds it impossible to void urine though the desire to do so is imminent. She knows of no cause whatsoever for her illness, and believes she lost at least 100 lbs. (?) since it began. She grew worse at the first hospital (?) (and no better at the second). Uranalysis at Roosevelt was negative (also on several later examinations at Vanderbilt Clinic laboratory). It appears, however, that after my first visit a number of uranalyses were made in which a "heavy trace to a cloud of albumin" was recorded, no sugar, never any casts, pus considerable, sp.g. 1017-1030. (Report kindly furnished by Dr. Martin.)

The facies of our patient showed no apprehension (in spite of the "brain tumor" and the advised operation) but looked flushed and "hysterical." This hysterical look was given by the eyes, the lids of which were not entirely raised ("pseudo-ptosis" one might have said). For her age, her face was also decidedly girlish or even childish, her lips constantly pouting. (This I later put down as "hysterical pseudo-infantilism.")

On examination, at this visit, I made the following notes: The head-contour was normal. There was some tenderness on pressure and percussion over the left side of the crown. No stigmata of lues or degeneracy were present. On standing with closed eyes, the patient swayed decidedly (on later examinations she even occasionally fell when tested). Her gait was decidedly and exquisitely cerebellar. On being told to close her eyes while walking she would stagger badly. Both at Roosevelt and at Vanderbilt Clinic it appeared to us that the patient's gait was much worse when she was being observed. She did not stagger to any particular side.

Vision tests showed (monocular) diplopia of the right eye (this had also been noted at the ——— hospital). On the left there was no vision at all in parts of the field, and the patient saw two objects as one (!) with this eye. Absolute shaft-vision obtained (using both eyes). There was also great and rapid vision fatigue. The color fields were irregularly inverted and much contracted. Ocular movements were normal. There was some nystagmus on extreme lateral excursions. There was no real ptosis (though it sometimes looked as if there might be. At all times the eyelids could be raised in the normal way if the patient was asked to do so). There was frequent and abnormal trembling of the lids. The pupils reacted normally to light and accommodation. The fundi were examined by Dr. Holden, who reported clear macula, no choked discs.

The sense of smell was absent on the right side. Motor and sensory fifth were normal. The corneal reflex was present and prompt. The facial seemed to show a slightly weaker innervation on the *left* side. (At the ——— Hospital it was found that the patient's mouth was drawn slightly to the left when smiling or whistling.) Cochlear and vestibular appeared normal. (Hearing test with fork and watch showed L<R.) The tongue, which was coated, trembled considerably at times and was anesthetic on the *right* half. It did not deviate. The *right* side of the mouth was also anesthetic. The pharyngeal reflex was absent. (This reflex, however, I find wanting in so many normal individuals that I do not lay much stress upon its absence.) The palate rose normally on phonation. Speech was entirely normal, though always a trifle hoarse. The neck (tonus, glands) and thyroid were entirely negative.

Examination of the upper extremities showed the following: There was a paresis of the *right* side. The right hand registered nothing with the dynamometer on the first test and only 3 K. on spurred effort. The left hand was also weak, though not as bad, registering 6 and 8 K. There was no spasm. Coordination was normal, also diadochocinesis. There was a strong, non-intentional tremor present, equal on both sides. Tactile, pain and thermal sensation were *completely absent* on the right side. (They had been only "diminished" when the patient entered the ——— Hospital.)

On testing for deep muscle sense it was my opinion that the patient was malingering. This was also the opinion of the house physician at Roosevelt. It was this, in fact, that made him suspect something functional in the case, and because of which he called me in to examine the patient. There was no pain on pressure over the nerve trunks. There were no trophic disturbances. Reflexes were normal (muscle and tendon). There were no contractures and no abnormal movements. *In spite of the absolute anesthesia on the right side, stereognostic sense was normal.*

The lower extremities, examined while prone, showed paresis and ataxia of the *right* leg. Asked to move the toes, the patient did so on the left, but scarcely on the right. The left side was entirely normal. There was complete anesthesia, analgesia and thermaesthesia on the *right* side. On testing for deep muscle sense the patient's responses again suggested malingering; in fact, this seemed almost positive. There was no pain on pressure over muscles or nerves, nor any trophic disturbance. The patellar reflex was present, not very strong, equal on both sides. The Achilles was present and normal on the right, but obtained with difficulty on the left. Babinski and Oppenheim were negative. The plantar reflex was brisk on the left, weak on the right side. There was no clonus.

The entire trunk showed the same complete sensory disturbance on the right side as did both upper and lower extremities. The abdominal reflex was not obtained (but this may have been due to the flabby condition of the abdomen).* The spine showed no abnormality. The report as to the visceral examination (examined at the hospital and later at Vanderbilt Clinic, and later again at other hospitals) was negative. The pulse was 96, regular, not very strong.

Mentally the patient appeared of moderate intelligence. Her memory (on tests) was excessively poor; otherwise the mental examination, rapidly carried out, however, was normal. There were no delusions, hallucinations, etc.

As to diagnosis, it was necessary in this case first to say whether or not a cranial tumor was present, and if so, to locate it, whether the hysterical symptoms were caused by the tumor (or whether we had a tumor here in an hysterical individual), or finally whether it was pure hysteria—and no tumor whatsoever. The question of nephritis would also have to be considered.

We concluded that this was a case of pure hysteria (plus renal disease?) and because of the following reasons: The absence of heightened reflexes and of clonus on the right side, and the *completeness* of the sensory disturbance (especially the complete involvement of the face, almost never found in brain tumor, also of the mucous membrane of the cheek, of the half of the tongue, and apparently also of the mucous membrane of the right nostril to smell—that of touch being maintained), argued against brain tumor. That the sensory disturbance should be so complete and yet no astereognosis whatsoever be present is also scarcely conceivable in brain tumor. Just this, however, is very common in hysteria. Some months later on examining the patient at Vanderbilt Clinic we could push a needle into the skin of her right hand without her feeling it, yet on this occasion stereognosis was normal *and electricity could also be normally felt.* One had to admit that none of the findings spoke absolutely for organic disease, and all could be accounted for by pure hysteria. The monocular diplopia, the seeing of two objects as one, the shaft-vision and contracted color fields, all spoke for hysteria. Inversion of the color vision, however, could not be used diagnostically as it has also been observed in brain tumor. The responses given on testing for deep muscle sense surely showed malingering (a condition observed often enough in hysteria).

Besides, the fundi were normal (examined on 2 or 3 occasions). Had abnormalities of the discs due to nephritis been present, the diagnosis would have been more difficult.)

(In preparing this history for publication, and only after the above had been written, further data concerning the patient's condition on her admission to the —— Hospital were very kindly supplied to

*The patient appeared to have lost some weight, possibly even considerable weight; but by no means the amount she thought she had lost.

me. As to the eyes, Argyll-Robertson pupils were noted, and beginning choked discs. Four days after, it was thought that the choked discs in both eyes were increasing. The veins of the right eye were much swollen and tortuous; small hemorrhages were present. The left eye showed "enormous size of optic disc." How shall we reconcile these diverse findings? Could a cyst filling, and being absorbed, or a meningitis serosa account for it? In the latter case where optic nerve changes occur, the headaches are often agonizing; and if choked discs occur they do not again disappear, or if the changes are inflammatory, even then the nerve does not so rapidly become normal. The first hospital findings were in August; normal backgrounds were reported at Roosevelt, in September.

A stereoradiographic examination of the head was also made at the first hospital and the bony structures at the base of the skull were found to be normal in contour. There were no bone defects. The sella turcica and mastoid cells were normal. A note was added that this examination excluded any brain tumor which was of a very dense nature or which contained any calcium salts; but that it did not exclude the presence of any cystic or soft tumors in the brain tissue proper.)

The patient was later discharged, and visited me on October 30. Her symptoms and signs were about the same. I induced her to come to the Vanderbilt Clinic where Dr. Starr was at the time lecturing on brain tumor, and she was shown to the students as a case of hysteria resembling brain tumor. All her symptoms were still "intact." I then began treating her with hypnosis* with apparently good result, for Dr. Starr was able to show the patient at his clinic one week later, with all her anesthesia, in fact all her sensory disturbances, gone. The paresis had also cleared up, and the grip was fairly good, though the dynamometer registered but 8 k. to 19 k. on that occasion. Headaches and vomiting, however, though improved, still persisted (these have continued to persist, at times getting worse, at times improving).

In the next week or two I tried to allay these symptoms with different methods, using mental therapy, drugs, electricity—all to no very good purpose. At this time the patient contracted a cold and took to bed with an elevated temperature. I sent one of my clinic associates to see her at her home. He reported that though he could hear only a few râles here and there in the chest and noted but little fever, the patient appeared quite sick and he suggested her going to St. Luke's Hospital, thinking she was making for pneumonia. Whether through the association of "hospital,"† or through the shock of the mild bronchitis her hysterical symptoms returned, cannot be said, but at any rate, the "tumor syndrome" came into evidence again and so convincingly that the receiving physician at St. Luke's (Dr. Lambert's service) at once diagnosed brain tumor and advised immediate decompression. Dr. Mount of St. Luke's was kind enough to give me the following facts concerning the patient's conduct while at the hospital:

She vomited practically every day and had to be catheterized most of the time. The urine at times had a trace of albumin, with hyaline and granular casts. Blood pressure remained at 160 systolic and 115 diastolic. Several Wassermanns were negative, even after a provocative dose of neosalvarsan. A luetin test was also negative. Lumbar puncture showed clear fluid, low pressure, cell count 10 per cubic centimeter, all lymphocytes, Wassermann negative. Nothing developed in the chest and the patient was discharged on February 24.

During the last week of her stay at the hospital the patient showed a strange mental condition which had not cleared up at the time of her discharge. She became rather noisy and difficult to control, apparently had some delusions of persecution (?), believed that all the patients thought she was pregnant or, at another time, that she was infected with syphilis. She said her sister was dead in the ward and that she was not permitted to see the body; talked about woman's suffrage; issued commands to children as though conducting a kindergarten, etc. [Nothing of this sort had been noticed before.]

A few days after, she again appeared at Vanderbilt Clinic. She knew nothing of having had any of the above delusions and acted no differently than when at our clinic previously. On treatment her general condition improved considerably and after a while I again lost sight of her.

On my return to the clinic in September, our patient showed up again. It appears that she had looked for me in the neurological room a few days before, and was seen by one of the men, who after examining her, gave her a slip which she was to present on her next visit. Her next visit, however, was to my psychotherapy room (at that time in the Applied Therapy Department). She showed me the slip with rather a peculiar expression on her face. The slip read, "examine for possible brain tumor." The patient told me she was again very sick, vomited, coughed, and had severe headaches, etc., all, she believed, brought on by some baths which had been prescribed for her. She very probably had taken cold.

Examination on this occasion (Oct. 12, 1914) showed the following:

Station and gait similar to former visits, though improved. Smell normal. Vision normal (the shaft-vision has entirely disappeared; no dyschromatopsia, no visual contraction, etc.). III, IV, and VI nerves normal. Reaction to light and accommodation normal. Occasional nystagmoid movements on extreme lateral ocular excursions. For the first time one notices a tendency to a positive Von Graefe (occasionaly met with in hysteria), but there is no Moebius or Stellwag. Looked at from above, the eyes protrude a very little (?). The lids "blink" excessively on closing. Corneal reflex normal. Facial is normal, the right innervation slightly stronger than the left. Motor fifth is negative. There is a "burning feeling" in the forehead. On the left cheek there is an irregular area of anesthesia.

The upper extremities: Movements, coordination, and diadochocinesis normal; but there is almost complete adynamia of the hands on *both* sides (with dynamometer: average of 2½ K. on the right and 1½ K. on the left). On the left hand the interossiæ evidence no power at all. Electrical examination of all muscles of hands is negative. Reflexes normal.

Sensory examination with needle and brush on the right side shows a complete and typical glove anesthesia and analgesia up to the wrist. On the forearm a few irregular small patches of anesthesia. The upper arm and shoulder are negative. On the left side there

*It was quite impossible to treat this patient with persuasion, direct suggestion, etc. One could not make any impression whatsoever upon her.

†According to Pawlow's studies on dogs (Vorlesungen, etc., Bul. d. Akad., St. Petersburg, No. 14, 1907) a non-related stimulus (β) through concomitance to (a) while (a) is producing the effect (c), may, after a brief time, become in itself a direct stimulus, acting precisely as (a). Hence ringing a bell will produce gastric juice in the dog if for a time he heard it ring while being fed. Mental associations may not in the same way (the psycho-reflexes of Bechterew), and (β) be made to associate (c) without the individual recalling (a) at the time. It is very probable that many of the symptoms and return of symptoms in hysteria may be explained in this way. How actual this mechanism is in the behavior of children, A. Czerny has pointed out.

is a glove anesthesia up to the wrist, a few very small spots of anesthesia on the forearm, and complete anesthesia and analgesia from the elbow to the shoulder. *Stereognostic sense on the right hand normal!*

On the left, astereognosis; but on suggestive treatment with electricity (high frequency) the astereognosis disappears immediately (test made with a piece of lead, coins, pencil, cotton, pen, etc).

The lower extremities were entirely normal.

The picture has now, one year later, lost its brain-tumor resemblance.

For a few days I lost sight of the patient, and then learned that she had been sent to Bellevue Hospital. It appears that she had had several "hysterical" attacks the night after she had visited the clinic, seemed very ill, and was sent by her family to the hospital. She came on Dr. Norrie's service—and Dr. Norrie at once diagnosed the case as hysteria. She remained two weeks—having an anuria during the entire period. She was allowed to go 56 hours on one occasion, without catheterization. The uranalysis showed some albumin, some pus, but no casts, sp. gr. 1030. The fundi were found normal. Color vision was considerably contracted, and general vision strongly on the nasal side. Another Wassermann was found negative.*

Again she returned to me—her hands now quite normal, but complaining of the same emesis and headaches, spots before the eyes, *and visions*. She saw faces, whether she opened or closed her eyes. These she knew were only fancies, yet they were there, nevertheless, and extremely distressing. This was her chief complaint on one or two visits.

The patient not returning, we made inquiry and were told that she had gone to friends in the country, and that she was feeling very much improved. As a matter of fact, however, our patient had gone to the Mount Sinai Hospital. This I learned much later, and only after the foregoing part of this paper had been prepared for publication.

Reviewing the case thus far, certain facts of interest may be noted. The diagnosis "brain tumor" in the first hospital made the patient worse. At Roosevelt she no longer had a hemihypesthesia, she had a complete hemianesthesia, etc. The bronchitis and examination by one of my associates and the transference to St. Luke's, and later again the slip of paper with "brain tumor" written upon it, made her decidedly worse. My own second examination (rather fully carried out, and made in the presence of a psychologist visiting the clinic), even though, remembering Babinski's admonition, I took great pains to avoid suggesting any symptoms *into* the patient, was followed that night or the next by "attacks" and a feeling of being very ill. Had the patient been neglected, had her various examinations been but superficial (a thing out of question, considering that brain tumor had to be excluded) she would probably have improved instead of gotten worse—for in several ways she did get worse. Her hypesthesia became anesthesia (this finally was cured by hypnosis). Later she had hysterical delusions, and when I last saw her, fancies of seeing faces. The headaches and vomiting continued. Are these latter due to some (intermittent) renal trouble? How shall we explain the divergent uranalyses at the various hospitals and clinics, some reports entirely negative, some noting albumen and pus, but no casts, again casts but no pus? Can we rely on the examination by internes who often are novices in the laboratories, and possibly more often overworked? But the ophthalmoscopic examinations in hospitals are usually made by ophthalmologists of experience. Can it be that what one sees with the ophthalmoscope is after all not a definite picture but something which must be "interpreted" and hence may be interpreted differently by different eyes? Think of the gravity of this! A diagnosis of choked discs means intracranial pressure, and this most probably means decompression, a most serious operation (and looking for a brain tumor fearfully serious). On the other hand, think how disastrous such an operation could prove to an hysterical individual—and our patient is that without question—and how many "post operative" additions might be linked in to the neurosis!

Finally, why do the hospitals discharge a patient directly the diagnosis hysteria is made? Is this not indeed a serious disease at times, and did not this patient of ours really need hospital treatment? I have found it quite impossible even to get my younger clinical charges taken into any of the hospitals when the diagnosis of hysteria was made. And yet, out of their homes, they could be so much more easily cured. And was not possibly some kidney abnormality neglected in the final conclusion that here was an hysteria? To many physicians hysteria is almost synonymous with malingering—and such a patient treated as if she were "putting on" or "imagining" her troubles. Hysteria, whether entirely functional or not, is surely as really pathological as is brain tumor. Lastly, what was the cause of so serious a disturbance in this apparently strong woman? Is some viscus at fault, or some abnormal process, waking up a congenital, latent hysterical disposition? Much remains unanswered in this interesting case—though I believe we may safely exclude the presence of a brain tumor.

It was after the above had been put together, that, as already mentioned, I learned our patient had been at Mt. Sinai Hospital (between October 30, 1914 and January 16, 1915).

Through the kindness of Dr. Sachs and Dr. Strauss an outline of the hospital record of the case was sent to me. From this very thorough account I shall be able merely to give the important facts.

The symptoms for which our patient sought relief were the same as in the beginning: headaches, projectile vomiting, and defective vision.

In the history given the patient maintained that she had been at St. Luke's Hospital, suffering from pneumonia (which, as we know, was not the case). The eye complaints referred now mostly to the left eye (in my own history it was the right eye that had been affected).

The sensory chart accompanying the Mt. Sinai history showed, indeed, the very remarkable fact that the sensory symptoms, formerly all noted on the right side, were now on the left side of the body! The patient staggered, falling to the left (this was noted several times in the subsequent history). There was lateral and verticular nystagmus. The right eye was somewhat sunken, tremor of lids. Reaction to light and accommodation normal. Corneal reflex diminished. Moderate stasis of lids. Weakness of right external rectus.

Tongue: marked tremor; ears: diminished hearing on the left side. Lungs, heart, liver, spleen: normal. Abdomen: pendulous; no tenderness. Reflexes: difficult to elicit.

Upper extremities: tremor, mostly right side. Weakness of left hand. Finger-nose test: overpoints to left. Adiadochocinesis.

Lower extremities: knee-jerk present, diminished, especially on right side. Achilles reflex diminished both sides. No abnormal reflexes. Slight tremor.

On November 2 there was noted astereognosis of left side, with loss of position. Right side normal. Slight facial palsy. Fundi normal (several examinations were made at this hospital, and with one exception, all reports were normal).

On November 3 the following facts were noted: Hoarseness, forgetfulness, head in cerebellar attitude, tendency to fall to left while seated. Cog-wheel phe-

*I am indebted to Dr. Norrie for these facts.

nomena both arms; most marked on right. Hemianesthesia left side; recognition of position present on right side. Imitation on left side poor. Sense of weight lost on left side. Flattening of right side of face. Faradic response of facial nerves equal both sides. Change of chronic catarrhal otitis media. Watch: right, ½; left, 3. Fork 512 lateralized to good ear. Air conduction within normal limits.

November 4: Complete fixation right half of larynx; right, recurrent paralysis. Patient says she has been constantly troubled with visions of cats, dogs, corpses, which she tries to drive out of her mind. No olfactory or gustatory hallucinations. Has auditory disturbances. Hears dead relatives converse with her, making references to her children and consulting her as to her husband's condition. The patient is fairly conscious during these hallucinations and tries to drive them away by covering face with her hands. Sees bright stars and lights, black circles like snakes, and tries to hide from them. An hour ago she saw children being brought in on stretchers.

November 8: Occipital headache, burning and hammering in character. All objects appear contracted. Vision normal. Choking sensations. For past three days generalized chilliness and elevated temperature (ranging between 99° and 101°). Has to be catheterized.

November 11: Lumber puncture. Five cubic centimeters of fluid obtained under 160 mm. pressure. Wassermann and globulin tests negative. No cells. Wassermann of blood also negative.

November 13: Patient attempts to get out of bed. Five minutes after knows nothing of occurrence (spell noted as of "epileptoid" nature).

November 14: Still has visions as before. Has fallen out of bed several times. Remembers nothing of this. Vomiting constant. Tremor as before. Occipital headache constant. *Urine shows albumin and casts.*

November 16: Left chronic Babinski position of toe. No Oppenheim nor Kernig. Distinct hypotonia and diminution of power in left upper and lower extremities. Weakness of right external rectus distinct. Hemianesthesia as marked as before. Symptoms point to a lesion involving right optic thalamus and posterior third of internal capsule and symptoms of cerebellar order. Double ptosis. There appears to be, by rough estimation, a right hemianopsia.

November 21: Quieter. Right facial hemispasm, followed by increased movement and then rigidity of right side. Marked increase in tremor on right side. Tremor of right face; right side catalepsy.

December 5: Ophthalmoscopic examination: Left fundus normal; right disk shows slight blurring at its upper and inner border. May be developing optic neuritis.

December 6: Difficulty in moving left lower limb. Burning sensation in entire right side of body. Difficulty in rotating head because of pains in back of head. Tremor of right upper and lower limbs. Cannot smell through left nostril. Memory failing.

December 9: Suddenly developed pain in right chest. Chills, fever, sweats, cough. Physical examination reveals a patch of dulness, bronchovesic. breathing and crepit. râles in lower right axilla. Temp. 102°, resp. 60; W. B. C. 12,000; polymorphonuclears 64 per cent.; lymphocytes 36 per cent.

December 10: Temperature, etc., as previous day. Resp. 32 (previously 60). Râles gone. Breathing diminished.

December 12: Ulceration of nasal septum on both sides.

December 14: Temperature normal. Pains worse. No signs present. Patient says she smells pepper.

December 17: *Patient was observed breathing. Respiration rate considerably increased. Later again observed (this time unawares), breathing found normal* (24). *When physician entered room again increased (to* 60). *Ten p. m. nurse takes respiration rate* (100). Pulse 90, and feeble. Occasional deep breath. Complains of a sticking in the left side of the chest. Nothing found. Patient acts peculiarly. Always wants physician. Asks for him constantly, asking foolish questions. Says she smells with one nostril; then the right half of body is numb, then the left. Hour after hour the physician is annoyed in this way.

December 18: Complete hemianesthesia, even nasal half. No Babinski. Nystagmus to left distinct.

The question comes up whether there is not a functional exaggeration of symptoms. After to-day's examination there is suspicion of a possibility that there may be an exaggeration of functional element in this case.

Though hemianesthesia present, patient, caught unawares, responds to pinprick. Tremor of left lower limb and even right brought on by suggestion.

December 19: Larynx cords fail to approximate with much more mobility on the left than right side, so that the condition is rather to be regarded as a double adductor paralysis than a recurrent.

December 21: Patient tumbled over sideboard and fell to floor. When asked why she did this she replied: "I was sending the children to school and wanted to get their rubbers." Asked how many children she had she replied: "How many do you think I have?" and burst out into hysterics.

December 31: Sat up out of bed; did not fall. Later asked to walk. Physician noticed that she would either attempt to fall or jump ahead when she thought she was not being noticed.

January 4, 1915: To-day symptoms appear largely functional.

January 16: Fundi normal. The following note: Patient first thought to have a lesion in the right optic thalamus involving the adjacent part of the intermediate capsule. It is now evident that condition is one of hysteria. Contracted fields of vision. Left hemianesthesia; pinprick not perceived as pain, but causes a reaction, *i.e. deep inspiration.* Many of previous symptoms have disappeared. Now able to walk. At times falls suddenly, apparently intentionally. Discharged improved.

I have not seen the patient again, and after considerable search, during the last year, have given up trying to locate her. It would be interesting indeed to learn how many more hospitals gave her a night's lodging and how this story ended.

60 West Eighty-fifth Street.

A REVIEW OF THE HISTORY OF CHEMICAL THERAPY IN CANCER.

By WILLIAM S. STONE, M.D.,

NEW YORK.

The presentation of a method of cancer therapy other than operation with the knife has usually been conceived either in ignorance or in the hope of financial gain. In the case of the chemical caustics, unfortunately for progress in the treatment of the disease, the unqualified condemnation of the manner of their exploitation has repeatedly prevented educated surgeons from learning how to use them and excluded a scientific study of their possible efficiency.

It is a remarkable fact that, so far as "cancer cures" relate to the local treatment of the disease, they have almost invariably been found to consist of arsenic, zinc, or the alkaline caustics. Arsenic is known to have been the effective ingredient of the applications made to cancerous tumors by the Indians, Egyptians, and Persians, and a salve, designated as Unguentum Egypticum, consisting of arsenic and vinegar, was in general use until the middle of the fourteenth century, when two notable surgeons of the University of Avignon, Henri de Mondeville and Guy de Chauliac, made efforts to improve the methods of diagnosis and treatment. Prior to this period it is clear that all classes of people—physicians, scholars, mendicant friars, and old women—treated all kinds of tumors with escharotic pastes and solutions, the most effective of which contained arsenic. The most skillful applications were undoubtedly made by the friars. The Hippocratic theory of the nature of cancer, "the atra bilis," was recognized in all therapeutic efforts, but exerted little influence on the methods of treatment. Diagnostic error, as a factor in the determination of successful results, applied alike to the use of the knife and to caustics. While

Galen and others of the Greek school supported this theory, two kinds of growth were differentiated: (1) the so-called scirrhus, which evidently included both benign tumors and the hard, slowly growing, and more definitely localized malignant growths; (2) those growths which were plainly evident to both patients and physicians as the more rapidly growing and destructive neoplasms. It is probable that chemical caustics were more generally used than either the knife or the heated iron, especially with the ulcerating growths.

Guy de Chauliac (1368), a great writer on surgery, as well as a skillful operator, directed attention to the use of caustics as an adjuvant to the use of the knife. He used arsenic mixed with clay and noted no toxic symptoms from its employment. Ambroise Paré (1510-1590), by his development of the use of ligatures and sutures, created a fresh enthusiasm for the use of the knife in the treatment of cancer, and, although using mild salves and solutions on ulcerating growths, tried to discredit the use of arsenic because of the baleful effects of its indiscriminate application. In Germany, Fabricius Hildanus (1560-1634), who was known as a skillful operator, and is reported to have excised the axillary glands in amputation of the breast, also tried to discredit the use of arsenic. We find, however, little evidence during the succeeding centuries that surgery profited much by the possibilities which the work of Paré and Fabricius had indicated. Clowes, physician to Queen Elizabeth, advocated as an additional therapeutic procedure the laying on of the Queen's hand. In Germany, theories regarding the nature of cancer simply became more numerous, and under the designation of "systems" their chief practical achievement was the exploitation of a constitutional cure in the form of conium maculatum by a Dr. Störck of Vienna, in 1761, an account of which eleven years later extolled its merits and the discoverer in terms of the highest praise. In 1779 a society in Bantzen offered a prize of 30 ducats for a cure of cancer without the use of the knife, mercury, cicuta, stramonium, belladonna, napello, and aconite, but there is no record of any award of the prize. In France the efforts to apply the recent discoveries in chemistry to the study of the nature of cancer had elicited the fact that tumors arise from the same tissue in which they appear. In 1773 Bernard Peyrilhe, in a thesis offered for the prize question by the Academy of Lyons, "Qu'est-ce le cancer," presented a scientific interpretation of the subject, and is credited with being the first to make use of animal experimentation in the study of the disease. The dog, however, into whose back the cancerous material had been injected, howled so continuously from the resulting lesion that its keeper removed him from the field of Peyrilhe's observations. In regard to treatment, he recommended for cancer of the breast the removal of the breast, excision of the axillary glands, and the removal of the pectoralis major muscle. For the treatment of nasal cancer he advocated the use of the recently discovered "kohlsäure."

The beginning of the nineteenth century was marked by efforts to overthrow ancient philosophy and medieval empiricism, and a new era in the conception and treatment of cancer appeared through the English and French anatomical researches. While John Hunter's (1786) lymphatic theory dominated the minds of the majority of the great surgeons, it included a new conception of cancerous growths as being the result of some vital activity on the part of normal tissues and subject to the same laws of life, growth and nourishment as the normal organism. In London (1771) the Middlesex Hospital had established a special ward for cancer patients, and in 1802 a committee of London surgeons was formed for the investigation of the nature and cure of cancer. During the three years of its existence its chief attainment was the distribution to the medical profession in England of an elaborate questionnaire, the result of which was as futile as it probably would be to-day if a similar method was pursued. Among the practical surgeons there were two factions regarding the theory of cancer—the "localists" and the "constitutionalists." The latter did not hold to a specific theory, but their ranks were largely derived from the orthodox surgeons of the day who had been so uniformly disappointed with the results of their operative work.

A publication by Young in London appeared in 1805 on cancer and the use of chemical caustics in its treatment, in which a remarkably clear summary is given of the fallacious arguments of those who maintained that cancer has a specific virus, is contagious or hereditary, and its action constitutional. His own conception of cancer presents with astonishing accuracy the present views of scientific men. "Morbid and natural structures, having the same principle necessary to each and governing both," he says, "a morbid alteration should never be viewed independently of the natural organization and functions of the part, or as beyond the laws of life." Briefly summarized, he considers cancer as a growth arising from acquired actions about a local structure that has been altered by injury or disease. On the recurrence of cancer, he says: "It must be obvious that the disease arises from such small beginnings, unfortunately, that it can never be detected until the obstruction has made considerable progress; and, as no specific virus is with it so as to offer any peculiar evidence from which one might take alarm, the disease thus proceeds securely in the minute parts of structure until such a circle of alteration is acquired as to make the change evident to the touch; so that when a surgeon takes out such a scirrhus tumor it is impossible to act beyond the reach of his perceptions, and to discover changes which can only be imagined, which may be there, or may not. . . . It is impossible to ascertain the distinct line between health and disease, and . . . some portions may be left, from which . . . the disease may ultimately recur."

Based upon this conception of the disease, Young directed the attention of the educated physician to the advantages which he believed the chemical caustics possessed if they were more discriminately and skillfully applied. He says: "It must be very evident to the most sanguine expectations that this disease, although the treatment of it in the future may be greatly improved, must still, in many instances, fall short of all possibility of cure. But . . . are we to relax in effort because effort is more required? Shall we withhold what *can* be done, merely because all that we wish *cannot* be done? Such, however, seems to have been the desperate sentiment in which science has left the disease almost to itself. It appears to have been considered as a thing so deeply rooted in its own sin and wickedness as to be beyond reprieve—a hardened malefactor, denied *every* consolation but that of the *knife*. This negligence on the part of science has given proportionate scope to the invention

of the quacks: they have seized upon the arms the regulars threw away, and have certainly played no unsuccessful part. Even old women, enlisted under the banners that were deserted, have proved at least (as far as their knowledge of the question went) that there is just as much orthodoxy in a piece of caustic as in a piece of iron."

As illustrating the attitude of the regular surgeon at that time toward the use of caustics, Young narrated the story of a published correspondence between two surgeons of the time. A regular surgeon, Mr. Guy, had purchased a nostrum, known as the "Plunket remedy," which he had been using extensively and apparently successfully without disclosing its composition, but claiming it had none of the qualities of a caustic. The surgeon to the King, Mr. Gataker, who, it afterward was ascertained, had also been using a caustic without the same success as had his colleague, publicly and vehemently denounced Mr. Guy because he was using a secret remedy. The efficient ingredient of the "Plunket remedy" was eventually ascertained to be arsenic. Young says: "Thus posterity seems equally obliged to these two gentlemen; to the one for condemning a thing which it is very evident he was totally ignorant; and to the other for the warm support of what it is equally clear he did not understand, or (which would seem still less innocent) of what he did not choose to understand." Young indicates that a more general use of caustics became introduced from this remedy, which considering the unqualified and indiscriminating way in which they were applied, were attended with more success, he says, than could have been looked for.

Young conceived that the advantage gained by the proper use of caustics was derived from their power of exciting newly formed tissues into an activity beyond their power, which is always less than normal structures. For this purpose he considered arsenic as particularly well suited because its action extended to all of the tumor tissue without rapidly producing a superficial eschar, the formation of which prevents the extension of the action to the deeper parts. An old preparation, known as Magnes Arsenicales, which he regarded as most efficacious, consisted of equal parts of antimony, sulphur, and arsenic, the antimony, he believed, adding to the extent of the area affected. Young urged the importance of applying treatment during the early stages of the disease, and, in order to avoid concealment of these tumors until it is too late, he writes as follows: "So long as the extirpation of scirrhi of the breast is performed by the knife, so long shall we have the disease fostered in secret, and, in too many instances, procrastinated beyond the point of safety, through the dread of an operation that is inevitably dreadful. For the operator may argue until doomsday ere he shall persuade his patient that cutting the breast with the knife is a mere nothing. . . . This rhetoric never gained a jot on the fears of ignorance, or on the quick feelings of diseased delicacy. The truth is that, when the operation is submitted to, the mind is seldom made up to it but as a last resort—seldomer from the convictions of reason, and never from an absolute command over the natural terrors of the heart."

There is no reason to doubt that Young's presentation of the subject had a favorable effect on the professional mind in both England and France. He was a graduate of the Middlesex Hospital, and, although not a member of the staff of that institution, he was a protege of Mr. Brodbeck, who made the first financial contribution to the establishment of its cancer ward. He became better known by a publication in 1815 on the treatment of cancer by compression, a method which received wide attention for many years. Récamier was enthusiastic about its efficacy, and devoted two volumes to a discussion of its principles and technical application.

From the beginning of the nineteenth century we find that all of the noted surgeons felt the need of some adjuvant to or substitute for the use of the knife, and until the last quarter of the century the use of caustics in cancer therapy was regularly discussed in the standard surgical textbooks. There are, however, few contributions to their technical application and very little discussion of the kind of cases to which they are applicable. Of all the noted surgeons of his time Velpeau seems to have made the most use of them, a paste designated as "caustique noir," consisting of concentrated sulphuric acid made into a paste, being his favorite formula. He says: "I have frequently employed caustics in the treatment of cancer, and I have frequently thought, I must confess, that they have more certainly prevented secondary cancerous affections in the neighboring glands than the extirpation with the knife. I have twice seen voluminous and indurated glands in the axilla diminish in a remarkable degree during the period I was destroying a cancer of the breast by caustics, and I have observed the same effect on the submaxillary glands, while cancer . . . of the lower lip was treated in a similar manner." Maisoneuve also refers repeatedly to the efficiency of caustics, especially of the chloride of zinc, in the removal of cancerous tumors, and of the long interval before they recurred. Dupuytren, as a part of his armamentarium, used a paste consisting of two parts of arsenic and 200 parts of calomel, which Parker refers to as generally too feeble in its action. Manec, of the Salpêtrière Hospital, Paris, used a paste consisting of one part arsenous acid, eight parts of cinnibar, and four parts of burnt sponge, made into a paste with a few drops of water. The results from its use were favorably commented upon by Lebert, who, Parker says, was not an ardent advocate of caustics. All of these cases had been referred to Manec by other distinguished surgeons as incurable.

Sir Astley Cooper is quoted by Parker as follows: "It behooves medical men to direct their minds to the trial of the numerous agents which chemistry and botany have lately abundantly discovered and simplified." Most of the pastes used during the first third of the nineteenth century consisted either of arsenic or the mineral acids, chiefly the former, and numerous accidents resulted from their use. Parker observed arsenic in the urine twelve hours after the first application, which continued to be detected during a period of eight or ten days. Toxic symptoms are recorded as occurring after the use of such strong pastes as the very old one, known as Frere Côme's, which is said to have cured Pope Gregory X of a cancer of the face. Maisoneuve mentions several cases in which its employment produced vomiting, precordial anxiety and other symptoms.

During the years 1834-1838 Canquoin of Paris reported the results which he had obtained from the use of a paste, the essential ingredient of which was chloride of zinc. He described four formulæ, as follows: (1) equal parts of zinc and flour; (2) zinc

one part, flour two parts; (3) zinc one part, flour three parts; (4) zinc one part, muriate of antimony one part, flour 1½ parts. Water from 20 to 30 drops for each formula. In 1838 a complete account of his results in 600 cases was published, in which the recurrences were given as 12 per cent. as compared with 75 per cent. after the use of the knife. Regarding the details of its application he says that formula (1) applied four lines in thickness for 48 hours destroys the parts to a depth of 1½ inches; that the same formula three lines in thickness applied for the same length of time acts only to about the depth of an inch. The depth to which the paste acts can, he says, with a little practice be regulated to the utmost nicety, depending upon its strength and the time it is applied. Plaster of paris may be substituted for flour, thus rendering it less delinquescent. The antimony was added in formula (4) to give it the same consistence as soft wax that it may be applied more uniformly over an unequal surface, such as is presented by an ulcerating growth. The advantage of the Canquoin paste over the arsenical preparations is attested by the fact that, with few exceptions, chloride of zinc has been the effective ingredient of all pastes since used by surgeons and quacks. Parker (1867) says: "The chloride of zinc will effectually remove the chief evil attendant on the application of caustic remedies to the destruction of cancerous growths—the amount of prolonged pain they occasion. It may be applied with a degree of precision unobtainable by any other caustic; it destroys the tissue in direct relation with the thickness of the layer applied; it never runs or fuses; it destroys only those parts which it covers, and these it divides from the surrounding structures as cleanly as though they had been cut with a knife. The crust or scab formed by this caustic is hard, dense, and white; there is no sanguinous or other discharge produced by it. The eschar separates at the end of twelve or fourteen days, leaving a clean, healthy granulating surface underneath." In 1855 there appeared in the *Dublin Quarterly Journal* a method introduced by Llandolfi, chief surgeon of the Sicilian army and Clinical Professor of Cancerous Diseases in the Trinity at Naples, in which he used bromine, either alone or in combination with the chlorides of zinc, antimony and gold. The introduction of this method was not enveloped in any mystery, and Llandolfi's personality and method of presentation produced such a favorable impression in Paris, Germany and Vienna through which he traveled that his paste was tried by many and used with considerable success.

The efficiency of chloride of zinc is illustrated by the story Parker relates of a Dr. Fell, an American, who went to London and so successfully treated numerous cases of cancer that a certain number of patients at the Middlesex Hospital were placed at his disposal under the condition that he reveal and publish the composition of his remedy. This was ascertained to consist of equal parts of chloride of zinc and a decoction of sanguinaria canadensis, with enough flour to make a suitable paste. The hospital staff were apparently favorably impressed with the results. A little later, a Dr. Pattison, a London homeopathic physician, in association with an American from Louisiana, vaunted a remedy as a sure cure for cancer without the use of the knife or caustics, the results of which had evidently obtained for the exploiters considerable fame and fortune. Their refusal to reveal the nature of their remedy prevented its being tried at the Middlesex Hospital, but it was subsequently found to be a combination of chloride of zinc and hydrastis canadensis. Both Fell and Pattison administered the "novelty" in their preparations also internally, the latter in a dilution commensurate with his homeopathic traditions.

It is clear that the staff of the Middlesex Hospital, as well as surgeons of other hospitals, must have had innumerable experiences of this kind, but the results were evidently sufficient to make the use of caustics—in the earlier years of arsenic, and later, after the work of Canquoin, of the chloride of zinc, an important adjuvant to the use of the knife. Moore and De Morgan, of the Middlesex Hospital, the former of whom is known especially for his work in the development of the radical operation with the knife, used weak solutions of chloride of zinc—20, 30, 40 grains to the ounce of water, after their cutting operations in order to destroy cancer cells that may have been disseminated through the wound or the neighboring tissues. De Morgan was so well satisfied with the improved results from this method that he expresses the hope that it will be more extensively applied. They found that the use of these solutions made no appreciable difference with the primary healing of their wounds.

A disadvantage in the use of the chloride of zinc was its failure to satisfactorily remove the normal skin over the tumor site, and for this reason in part the alkaline caustics and mineral acids retained their vogue. The well-known Vienna paste consisted of five parts of potassium hydrate and six of quick lime. The "Filhos" caustic contained the same ingredients in different proportions, and was fused and run into leaden tubes like nitrate of silver or potassa fusa. Of the mineral acids, nitric acid was introduced by Rivallie (1850), in the form of monohydrated nitric acid made into a paste with scraped linen or charpie. For cancer of the servix uteri, Routh (1866) advocated to the Obstetrical Society of London the use of bromine—five grains to the ounce of spirits of wine. Tilt indicates that in his hands and others the application of the acid nitrate of mercury to a cancer of the uterus produced satisfactory results.

Reviewing the situation from the text-book literature of the sixth and seventh decades of the nineteenth century, we find Thomas (1869) expressing the opinion that, if it should be impracticable to remove completely a cancer of the cervix by amputation with the ecreseur, scissors, or the galvanocautery, it should be destroyed as completely as possible by the actual cautery, potassa cum calce, or one of the mineral acids. Erichson says: "The employment of caustics . . . requires neither knowledge of anatomy nor of operative surgery, and so they have always been popular with many who would hesitate to use the knife. In this country, however, . . . they have not perhaps been legitimately employed to the extent they deserve. The chief argument in favor of caustics is that when cancers are thus destroyed they are less liable to relapse than when extirpated with the knife. There is, however, no positive proof of this before the profession; but it is not improbable that the chemical action of the caustics may extend so widely into neighboring structures as to destroy or render unproductive the cancer cells by which they are infiltrated, and on the development of which the local recurrence of the disease depends. Another advantage urged in favor of caustics is that enlarged

glands are more likely to go down under their use than when the primary cancer is extirpated by the knife." In 1872 Bougard, a prominent Belgian surgeon, wrote most enthusiastically of the advantages in the use of caustics, stating that recurrences were less frequent than after the use of the knife. His formula, consisting largely of chloride of zinc with a small amount of arsenic, was used by numerous surgeons for several years. Willard Parker (1873), in a paper on cancer of the female breast, says: "In the superficial cancer of the breast it is very well to use caustics. The same thing might be said with regard to cancers upon the face. The treatment with caustics in that region is good surgery. When the tumor is situated to any extent below the surface, the idea of caustics is bad surgery." He referred to two cases of fatal poisoning from their use. In the discussion of this paper Fordyce Barker says: "Because of the general use of caustics by charlatans a great majority of the surgical world have been satisfied with regard to their uselessness. My own prejudices have always been against this method of treatment." As a result of his observations in the St. Bartholomew's Clinic in London, the whole process seemed so revolting that he did not pursue his investigations further for some time. In 1870, however, he became so pleased with the work which he saw in the London Cancer Institute by Marsden that he applied this method of treatment successfully in two cases—one a cancer of the breast in which an operation with the knife had been refused, the other a cancer of the cervix uteri. He used the Marsden paste, which consisted of equal parts of arsenious acid and acacia. Sands, in his discussion of Parker's paper, said that he had had no experience with the use of caustics, but used the knife for the following reasons: (1) Nature of the tumor can not be determined prior to its removal; (2) now and then undoubtedly a malignant tumor is cured by operation; (3) expediency. J. Collins Warren says: "I have had little experience with the use of caustics. I find little difficulty in persuading patients to resort to more radical measures." About the face, to rodent ulcer, he preferred the use of the cautery, especially near the angle of the eye, because there resulted less of a scar, it being more difficult, he thought, to be economical of tissues with the knife, and more deformity resulted than when nature is allowed to borrow skin from all directions.

Stephen Smith (1880) describes his use of the anhydrous sulphate of zinc in the form of a powder, using a strong sulphuric acid paste for the removal of the skin. He says: "This remedy, though all but discarded by surgeons in the treatment of cancer, has a place in the therapeutics of cancer not yet accurately defined. It is one of the destructive measures which we may resort to, having capacities limited only by the possibilities of its application. As ordinarily employed, its real virtues are not fairly nor adequately defined. We are advised, or rather permitted by authorities to apply caustics to ulcerated cancerous surfaces, the growth no longer being amenable to the knife. That is, caustics are recommended as a last resort, when the disease has taken such deep root that it is certain to prove fatal. If useful under such circumstances, may they not be far more serviceable at an earlier period? In my experience caustics judiciously selected and thoroughly and persistently applied give the best results of any method of treatment yet adopted." Dabney (1882) also reports favorable results from the use of this powder. Billroth (1889) expressed his preference for the use of the knife, but in very old, anaemic, or timid patients, thought caustics may be employed, and, if the treatment be continued until all the diseased portion is destroyed, the result will be favorable. "Physiologically," he says, "caustics would have some advantages; for it is supposable that the cauterizing fluid may enter the finest lymphatic vessels, and thus more certainly destroy the local disease. But this does not occur readily, because the tissue with which the caustic comes in contact instantly combines with it, and its further flow is thus prevented." For a caustic Billroth preferred chloride of zinc. Robinson (1892), in discussing the treatment of cutaneous epitheliomas, says that caustics with less scar remove more tissue than the knife. He used caustic potash and the formula of Bougard. Lewis (1893) used the Marsden paste for a number of years in the treatment of superficial cancer of the skin. Snow (1893) writes of the advantages obtained in the use of caustics on small superficial lesions, and in chronic epitheliomas, or rodent ulcers. He considered potassa fusa to be the most thorough and rapid, its action being instantaneously checked by the use of water, and causing no subsequent pain or shock. Parmenter (1894) says that it has not been proved whether caustics are better or worse than the knife, but he believes that the intelligent application of a proper caustic to easily accessible and definitely localized tumors, such as those of the skin, lip and external ear, has many advantages. Bulkley (1894) has found use for Marsden's paste, the potassa fusa, and Bougard's formula in early superficial malignant growths. Allen (1904) takes exception to White's statement that "the caustic treatment in the form of injections, pastes, and all other kinds of mixtures, rarely prove of any service, and usually only deceive and render more uncomfortable the existence of a patient. They have been discarded by almost all except charlatans." Impressive evidence of the value which the proper application of caustics may still possess in cancer therapy is furnished by the following words of Halsted (1907), in a paper on Carcinoma of the Breast: "I am indubitably convinced that the local and regionary recurrences after incomplete operations, which come with amazing rapidity when the knife has been used, are, to say the least, relatively late in making their appearance when chemical or actual cauterization has been employed. I have several times had to operate upon cancers which had been vigorously and repeatedly treated with caustics, and to note the comparatively admirable condition, the freedom from cancer premeation of the surrounding tissues and of the axillary nodes; whereas, after incomplete operations with the knife the local manifestations of recurrence were almost invariably deplorable and the prognosis, of course, invariably hopeless." He also says, "I doubt if any melanotic tumor of the skin should be removed with the knife."

From this review we learn that since the beginning of the nineteenth century chemical caustics were an increasingly valuable resource of all the noted surgeons in cancer therapy until Langston Parker (1867) in the Annual Address in Surgery, before the British Medical Association, showed that they had become a fair rival of the knife. In spite, however, of the undoubted success which attended their use during this period, we find that they were being applied less frequently by the skillful surgeons during the last quarter of the century. During the

early years of the twentieth century their position in cancer therapy is not unlike that described by Young over one hundred years ago. "Caustic applications," he says, "were ushered in under the equivocal sanction of a nostrum, they were pursued as a nostrum, and then they were turned out as a nostrum. All regular inquiry has been withheld from the merits of the practice, and because it did not succeed in all things its efficacy was not allowed to any. Thus transferred from the irregulars to the regulars it was turned back to its original holders."

In the light of this history it may not be unprofitable to ask if they have a field for use at the present time?

Regarding the continuation of their use by the "original holders," we may hope that our educational propaganda and a more intelligent legislative restraint will ultimately solve that part of the problem. The question of renewal at the present time of the consideration of their efficacy by the educated surgeon naturally reverts to an estimate of their value when previously used and to the reason for their abandonment.

Their value as compared with the operation by the knife was apparently not satisfactorily defined at the time they were given up. No statistical data were available. We know that operations with the knife during a greater part of the nineteenth century were almost invariably incomplete and that the cures were few. Sands says, "Now and then a cure was accomplished." After the use of the chemical caustics, however, we have the evidence of numerous competent observers that the interval before recurrences appeared was often long, and there is much reason to believe that cures were more frequent than after operations with the knife. The danger from poisoning was made a negligible factor by the very general substitution of zinc chloride for arsenic.

We do not find therefore that their value in the hands of competent surgeons was discredited, but the reason for their abandonment appeared to be in the new conception of the possibilities which scientific medicine furnished to the practical surgeon during the closing years of the century. Pathological anatomy was making an early and exact diagnosis more available, the results of bacteriological research promised to make primary mortality a negligible factor and primary healing of the wound a definite certainty, thus encouraging the surgeon to believe that ultimately the development of his technique would preclude the necessity of using chemical methods which were less attractive and extremely difficult to apply. Frequent and early recurrences could not obliterate the attractiveness of the primary result, and, until the past decade, sufficient solace could always be obtained in the idea that constitutional taint or heredity were compelling factors in the unfavorable progress of the disease.

The result is that the "salvage," as expressed by Clark in regard to uterine cancer is greater, but, owing to our failure to increase appreciably the number of patients applying for treatment in the earliest stages of the disease, the primary mortality has markedly increased, operative sequellæ are frequent, and recurrences are still discouragingly large. The words of Peterson (1912) are important, who, after expressing his strong belief in the radical operation for carcinoma of the uterus, says, "My added experience has not made me any more confident that the next patient I operate upon will either survive the primary operation or will ultimately be cured." Finally, there is the important fact that the availability of surgical skill sufficient to effect a respectable salvage is extremely limited—as much so as is that of radium.

We believe, therefore, that the evidence of the value of chemical caustics is sufficiently strong to justify a new study of their technical application and a discussion of the kind of cases in which they may be most efficiently applied. In so doing they may afford a valuable adjuvant to the use of the knife and become applicable to a number of well developed growths, the extirpation of which at the present time results in a high primary mortality and a high percentage of recurrences.

Regarding the educational propaganda of cancer, it seems to the writer that the study and application of all reasonable methods of treating cancer will be of aid in encouraging the public to seek early relief from competent hands. While anaesthesia and skill have diminished the dread of the knife, the fear of an operation still remains an important reason for the frequent delays in asking for advice.

CYSTOSCOPY AS A DIAGNOSTIC AID IN SPINAL CORD DISEASES.

BY GEZA GREENBERG, M.D.,
NEW YORK.
CHIEF OF CLINIC OF THE GENITO-URINARY DEPARTMENT OF THE NORTHWESTERN DISPENSARY; ATTENDING UROLOGIST GERMAN HOSPITAL DISPENSARY.

IT has long been known that lesions of the spinal cord give rise to bladder disturbances, in some cases early, while in others late in the disease. This is due to the innervation of the bladder. The lower the lesion in the cord the earlier the symptoms.

To understand fully the mechanism of it it is necessary to describe the anatomy and physiology[2] of the bladder. The bladder is a muscular organ serving as a reservoir for the urine until it is fully distended, when it empties itself completely; this process repeats itself at regular intervals. It is an elastic body made up of a mucous layer of transitional epithelium, a muscular coat arranged in three incomplete layers, viz., an outer longitudinal, a middle circular, which is strongly developed at the internal sphincter, and an inner longitudinal; the outermost layer is the serofibrous coat. There are motor and sensory nerve ganglia in all the three coats. The plexus supplying the bladder is called the vesical plexus, which is an offshoot of the hypogastric plexus of the sympathetic nervous system. The hypogastric plexus divides into the pelvic plexuses and these in turn give off plexuses to the various viscera, to wit, the vesical, prostatic, seminal vesicle, and cavernous plexus. The various plexuses are connected with one another by means of ganglia, and with the sacral nerves by the rami communicantes; and lastly with the lumbar nerves through the hypogastric nerves and the inferior mesenteric ganglia.

In order to get perfect contraction of the bladder the afferent, central, and efferent neurones must be intact. It is still a mooted question how the process of micturition takes place. According to Goltz[3] the series of events is as follows: The distention of the bladder by the urine causes a stimulation of the sensory fibers of the organ and produces a reflex contraction of the bladder musculature, which squeezes some urine into the urethra; this in turn stimulates the sensory nerves in the urethra, giving rise to a desire to urinate. If no obstacle is present the bladder empties itself, aided partly by the abdominal muscles and partly by the bulbocavernosus. The emptying of the bladder can, however, be prevented by the voluntary contraction of the external sphincter, thereby counteracting the contraction of the detrusor muscles of the bladder; and if the bladder is not too full, then the desire will eventually pass off. Hence it is seen that the voluntary control of the process is limited to the action of the external sphincter and the abdominal muscles, while the contraction of the bladder itself is an unconscious reflex act taking place through the sacrolumbar center. Goltz and others proved by severing the spinal cord in a dog at the junction of the thoracic and lumbar regions that micturition still took place, and that it was a reflex act with its center in the lumbar region. The same author adduces evidence to show that the sensation to urinate and of fullness comes from stimulation in the bladder itself caused by the pressure of the urine. He points out that the bladder is very sensitive to reflex stimulation; that every psychic act and sensory stimulus causes a contraction and an increased tone of the bladder. The bladder is subject to continual changes in size from reflex stimulation, and the pressure within it depends not only on the quantity of urine, but on the condition of bladder tonicity as well. It is easy to understand from this viewpoint how it happens that we may at times have a strong desire to urinate with but little urine in the bladder—for instance, under emotional excitement.

Again Langley and Anderson[4] have shown by experiments on dogs, cats, and rabbits that the bladder receives two sets of motor fibers; first, from the lumbar nerves, the fibers passing out in the second to the fifth lumbar nerves and reach the bladder through the inferior mesenteric ganglion and the hypogastric nerve; second, from the second to the third sacral nerves, being contained in the nervus erigens. Stimulation of the hypogastric nerves causes comparatively feeble contractions of the bladder, while that of the nervus erigens brings forth powerful contractions.

According to Nawrecki[5], the spinal sensory fibers to the bladder are found in the posterior roots of the first to the fourth sacral nerves, and when these are stimulated they reflexly stimulate the anterior roots of the second and third sacral nerves, these being the motor fibers.

The bladder is governed by the same laws of physiology as all other striped and unstriped muscles, the vitality of the tissues depending on the uninterrupted nerve supply, while that of the nerve fiber on the integrity of its cells and ganglia. If a nerve be cut, the part which is separated from the cell degenerates. The irritability at first increases, but soon diminishes, being wholly lost in three to four days. As the nerve regenerates, the irritability returns gradually, and not until the axis-cylinder has grown down into the fiber is the nerve capable of responding to induction shocks. The muscle will likewise be affected; at the end of a fortnight the irritability of muscle lessens. For

about six to seven weeks the response to mechanical irritants and direct battery currents increases, while to the faradic current diminishes; then the irritability lessens progressively until it is entirely lost at about the eighth month. This is followed by muscular degeneration.

When the posterior spinal ganglia are diseased as in tabes, the posterior columns degenerate; in the course of time the ganglia themselves atrophy. The peripheral nerves undergo some changes the process of which is not thoroughly understood. As a result of all these changes the arc of conductivity is broken, and the deep reflexes are either diminished or completely abolished. When during this process the bladder centers are involved, then the sensitiveness of the bladder will be reduced to such an extent that the desire to urinate will not arise until there is more than the average amount of urine in the bladder. This finally results in vesical distension, and the process of micturition will more than ever be executed by the will, since the fibers from the anterior horns are not affected at all. The contractions of the feebler and the emptying of the viscus is largely carried out by the aid of the abdominal muscles. In the course of time secondary changes in the bladder and kidneys will follow stagnation and infection. Imperfect contraction of the bladder musculature is probably just as much responsible for circulatory disturbances in the bladder wall as the residual urine. However, long before symptoms of infection manifest themselves marked changes in the bladder take place. The changes are not unlike those found in heart diseases where dilatation and hypertrophy go hand in hand. Owing to the peculiar arrangement of the muscle bundles in the bladder wall, where they run in various directions, some of these muscles become markedly hypertrophied and project into the lumen of the viscus, resembling the fleshy columns of the heart. In some places numerous diverticulæ of different sizes result from it. In spinal cord cases I found the trabecular and the diverticular formations more commonly on the roof and lateral walls than on the fundus, while in cases resulting in similar changes from long-continued obstructions due either to hypertrophied prostate or to an impervious stricture, I found them more often and better developed on the fundus of the bladder. As the disease progresses the muscle fibers atrophy and degenerate, resulting in atony of the bladder. When this stage is reached the bladder becomes enormously distended and then an overflow (incontinence) follows. When the lesion starts in the anterior horns, then the atrophy and muscular degeneration set in earlier, resulting in incontinence due to paralysis of the sphincter.

All these changes occur in practically every cord lesion where the sacrolumbar segment is diseased, but the time of occurrence depends on the extent and progressiveness of the lesion. As a rule the urinary symptoms arrive late in the disease, although their early presence may be overlooked by the symptoms of palsy. Occasionally one may see a patient with no symptoms referable to the cord but to the urinary organs, namely, difficulty of micturition, and on examination find a considerable amount of residual urine. Cystoscopy in such cases shows marked trabeculations and diverticulæ formations.

When one finds such a group of symptoms in the absence of any physical signs pointing toward a stricture or an hypertrophied prostate, even though there are no signs other than urinary, one may reasonably suspect an oganic disease of the cord. The lesion may have started in the bladder center, but it has not advanced far enough to give evidence of other forms of paralysis.

It behooves us, therefore, in every patient who presents himself with urinary disturbances to examine his nervous system, and if no signs be present, provided the local condition is not accountable for it, to cystoscope him, and if such physical signs as I have just described are present, and if they in addition are associated with chronic constipation which started at about the same time as the urinary difficulties, then it is almost certain that the patient is afflicted with a grave nervous lesion of the cord, which will sooner or later manifest itself with all the other characteristic symptoms.

The following cases will illustrate the effects of cord lesions on the bladder:

Case I.—B., 34 years, denied venereal history; presented himself for difficulty of micturition and a small stream. Urethra and prostate normal. Residual urine 12 to 16 ounces. Cystoscopy showed a markedly trabeculated bladder with numerous diverticula on the roof, lateral walls, and fundus. His superficial reflexes were present, but the knee jerks absent; pupils reacted sluggishly to light. He had no ataxia; marked atony of the rectum. Wassermann negative. I followed him up for about three months with no improvement in his condition. His lesion probably started in the sacrolumbar region about the bladder and rectal centers before invading the other parts.

There is another class of patients who have absolute loss of sphincteric control caused by either a paresis of the sphincter or exaggerated reflexes in the bladder, where a few drops of urine are sufficient to set up contractions in the bladder, or, perhaps, by a combination of the two, as might occur in ataxic paraplegia, where the lesions are in the dorsal and lateral columns of the cord.

Another illustrative case showing an absolute paralysis of the sphincter:

Case II.—A young man of about 26 came to me with the following history: About five months prior to this he became paralyzed in both legs, this being followed two months later by incontinence of urine. He wore an improvised urinal for the relief of this condition. On examination I found the head of the penis and part of the frenum were macerated, and sloughing on account of the irritation by the escaping urine. Cystoscopy was futile on account of the sphincteric paralysis, and the bladder could not be distended. He had atrophy of his limbs with loss of reflexes. His lesion was in the anterior horns.

Case III.—M., 27, had gonorrhea but no syphilis; used alcohol excessively. He presented himself for treatment for what he thought was gonorrheal arthritis and a weak bladder. He complained rather of stiffness and weakness in his right hip and knee than actual pain. On examination I found a spastic gait, fibrillary contractions of his right thigh muscles, marked increase of both knee reflexes, no ankle clonus; no ataxia of his arms or legs; pupillary reflexes normal; loss of temperature sense in his right leg and foot. Wassermann negative. He had difficulty in starting to urinate, and had nocturnal enuresis. At times he lost his sphincteric control of both bladder and rectum; at other times he had frequency caused by an overdistended bladder. Examination of the urethra showed an annular stricture of 22 French calibre at the penoscrotal junction; residual urine eight ounces. Cystoscopy revealed marked trabeculations of the bladder. In this case the trabeculæ could not be attributed to the stricture alone, for it was of a fairly large calibre; and had they been caused by the stricture without any cord lesion, then there would not have been any residual urine in the bladder, for young healthy individuals even though they develop such marked changes in the bladder from impervious strictures, regain the normal tone of the bladder as soon as the obstruction is removed and practically expel every drop of urine. He sustained

a severe burn of his right foot while bathing it, due to his loss of temperature sense.

THROMBOPHLEBITIS IN THE TUBERCULOUS, WITH AUTOPSY.*

By ETHAN A. GRAY, M.D.,

CHICAGO, ILL.

MEDICAL DIRECTOR, CHICAGO FRESH AIR HOSPITAL.

While thrombophlebitis is of every day occurrence, its incidence in the tuberculous appears to have escaped the attention of writers on tuberculosis. And yet, even as a complication of tuberculosis, it is not rare. We have observed it at the Chicago Fresh Air Hospital no less than seven times in 1400 cases.

My material comprises three men and four women patients at the Chicago Fresh Air Hospital; three of the women were in the far advanced stage of their disease, as was the fourth, who was, however, of the chronic type; the three men and two women had thrombophlebitis of the lower saphenous of both legs.

One woman (autopsy) had thrombosis of the inferior vena cava and of both iliac veins. One woman developed thrombophlebitis of the arm which extended upwards into the external jugular vein. In the cases of the two women and three men the phlebitis began in one leg and, after subsiding here, attacked the other leg. The patient with thrombosis of the basilic and jugular improved after leaving the hospital. No subsequent history was obtainable except that she died some months later. The other women died with thrombophlebitis still active. One man is well, his pulmonary condition under control by artificial pneumothorax; he is working steadily as dining-car conductor; the second man is an invalid but free of vein symptoms; the third man is convalescent as regards his pulmonary condition, his thrombosis being manifest only through the thickened veins, palpable under the skin.

Case with Autopsy.—Mrs. D. S., age 30, housewife, was admitted to Fresh Air Hospital, May 21, 1914. Father living and well, mother died of "dropsy." Patient has had three children, one dead born and twins which died aged 3 days and five weeks, respectively. Patient has had rheumatism. Five years ago the "present trouble" (pulmonary tuberculosis) began with cough; bleeding from the lungs has occurred several times; there have been night sweats. Patient is constipated and suffers from "stomach trouble;" appetite bad; menses absent. Appearance of patient cachectic; face sallow and much emaciated.

Sputum contains tubercle bacilli corresponding to Gaffky II, urine cloudy, sp. gr. 1020—some albumin. Pulse 112; temp. 39.2° C. Blood pressure, systolic, 79.

Physical examination. — Right Lung—Anteriorly: Amphoric respiration, Moist rales, Wintrich sign I, II, I. C. S.; Tympany down to III rib.

Posteriorly: Tympany, Amphoric respiration from apex to III rib.

Left Lung Anteriorly: Amphoric respiration, apex to IV rib.

Posteriorly: Cavernous respiration with amphoric character II—IV ribs, creaking and moist rales.

*Read before the German Medical Society of Chicago, April, 1915.

June 15, 1914, the patient was attacked by severe pain in the left leg. On examination there was found redness along the long saphenous vein which was painful on pressure. June 20, the inflammation was recognizable in the femoral vein. July 1, the pain was less and on the 11th of the same month was nearly gone. August 1 pain was felt in the region of the inferior cava which was aggravated by deep pressure over the vessel; pressure also elicited pain in the pelvis.

Diagnosis: thrombophlebitis of the iliac veins.

On September 1 the disease attacked the long saphenous of the right leg. From this last named date until her death, October 1, the patient was never free from pain; temperature was constantly around 38.5° C.

Autopsy (by Dr. Olga Pickman). Body of an extremely emaciated woman; hips and abdominal walls very edematous, feet and lower legs edematous. The saphenous and femoral veins were felt, cordlike, under the skin.

Thorax: Left, many pleuritic adhesions, extensive consolidation; several walnut sized cavities in both lobes; much scar tissue—Right lung: here, also, many cavities and extensive consolidation; the lungs were heavy as the result of much cicatrization. Heart small, musculature pale and flabby, valves competent.

Kidneys congested and degenerated (fatty). Spleen congested and enlarged. Liver congested and degenerated.

A piece of the long saphenous vein of the right leg was removed, the vein found to be thickened and entirely filled with thrombus. The left leg was not examined. The inferior vena cava was smaller than usual—thickened and partly blocked with thrombus, the clot extending down into both iliac veins from the cava; the lumen of the cava, as of the iliacs, was also about one-half filled by the thrombus.

Miscroscopical: The excised portions of the veins were examined by Dr. Oscar Nadeau, to whom my thanks are due. The specimens were stained with carbol fuchsin for tubercle bacilli which were not found, however, by this method. With the picrin stain, a few tubercle bacilli were found in the thrombus. In one section a bacillus was found in the intima of the iliac vein. With the Much stain, granules were found in many sections of the vena cava.

Bacilli are not constantly found in the circulating blood. According to the observations of various students of this subject, the blood may be flooded with tubercle bacilli in the death agony. It is not certain that the bacilli circulate in the blood in moderate infections. Brieger, experimenting on guinea-pigs, found that the bacilli were solitary in the blood, never in clumps. Also, in his experiments, he determined that the intravenous inoculation was mostly negative.

Klopstock and Seligmann (*Ztsch f. Hygiene*, Bd 76 H. i.) examined the blood of four consumptives. In no case did they produce definite signs of tuberculosis in guinea-pigs by the inoculation of these bloods. Bandelier and Roepke refer repeatedly to the presence of tubercle bacilli in the circulating blood in far advanced cases and cite the occurrence to explain tuberculous infection of other structures.

It will thus be seen that variance of opinions exists regarding the infectiousness and incidence of tubercle bacilli in the blood stream.

Nevertheless, infection of the venous vessels in the tuberculous is here shown to be of sufficiently frequent occurrence to give rise to inquiry as to the mode of production.

2744 Pine Grove Avenue.

Alcoholic Insanity in Kansas.—Newcomb states that but 1.7 per cent. of insane committed in Kansas during 1915 were suffering from uncomplicated alcoholic insanity. He contrasts this figure with the general average of 10 per cent. throughout the country, some special hospitals giving a minimum of from 4 to 5 per cent. The incidence in rural communities of alcoholic psychosis is very low—2.6 per 100,000 inhabitants—and it may be urged that Kansas is much more rural than urban, but about half the cases came from counties adjoining wet States.—*Pennsylvania Medical Journal.*

A CASE OF PAN-SINUSITIS, COMPLICATED WITH ACUTE SUPPURATIVE APPENDICITIS AND ACUTE MASTOIDITIS.

By JOSEPH EASTMAN SHEEHAN, M.D.,

NEW YORK.

INSTRUCTOR IN DISEASES OF THE NOSE AND THROAT, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; CONSULTING EAR AND THROAT SURGEON, ST. FRANCIS' HOSPITAL, PORT JERVIS, N. Y.; ATTENDING EAR AND THROAT SURGEON, ST. MARY'S HOSPITAL, ORANGE, N. J.

THE following case seems to be worthy of permanent record:

Miss M. H., age twenty-six, consulted me July 23, 1915 for a continual discharge from her nose. For the past two years she has had more or less continual discharge from the nose of a purulent nature. During the past eight months she has complained of headaches, principally on awakening in the morning, of a frontal character, which lately have become occipital, and which were gradually getting worse; they would last well into the afternoon. Coughing with expectoration followed with loss of weight amounting to eighteen pounds within one year. The past history reveals nothing of importance. Her father and mother are alive and well, and two brothers and one sister are still living.

Examination shows a pale girl with drawn features and an anxious expression. There is extreme tenderness over the right frontal sinus with swelling and tenderness over the right antrum. The left frontal sinus and antrum also are somewhat tender to pressure. Transillumination reveals dark shadows over the antra and both frontal sinuses.

Examination of the nares showed much mucopurulent discharge with markedly enlarged turbinates, and there was a high deflection of the septum. Probing both sphenoidal cavities showed that they were diseased. The antra were opened and found to contain pus. The patient was advised to go to the hospital and submit to an operation. She agreed and an operation, followed by many more, resulted.

Herewith is the blood picture: Blood Wassermann negative. Complement fixation test for gonorrhea negative. Luetic test, negative. Von Pirquet and Morro reactions negative.

Blood Count: Hemoglobin, 60 per cent.; red corpuscles, 2,800,000; white corpuscles, 13,000; polys, 72 per cent.; small lymphocytes, 16 per cent.; large lymphocytes, 10 per cent.; eosinophiles, 1 per cent.; transitional cells, 1 per cent. No malarial parasites.

The smear of discharge from the nares showed a staphylococcus and a streptococcus with a large bacillus present. A combined vaccine was made and given with little or no effect on the discharge.

The sputum was negative for the tubercle bacillus. The urine showed a faint trace of albumen. There were no casts present.

On August 15, 1915, both middle turbinate bones were removed with a total eradication of the anterior and posterior ethmoid cells on both sides. These cells were found to be wholly diseased. Both frontal sinuses were opened, irrigated, and drained, much purulent matter being exuded. The smear of the frontal sinuses showed a staphylococcus, a streptococcus, and a small bacillus present.

On September 13, 1915, both inferior turbinate bones were removed and the antra opened and curetted. The sphenoid cavities were opened also and curetted. For three weeks following injections of arsenic and iron were given.

On October 5, 1915 the blood examination showed the following result: Hemoglobin, 75 per cent.; red corpuscles, 3,200,000; white corpuscles, 11,000; polys, 69 per cent.; small lympocytes, 21 per cent.; large lymphocytes, 8 per cent.; transitional cells, 2 per cent.

On November 5, 1915, both frontal sinus openings were enlarged. The smear showed a streptococcus, a staphylococcus, and a small bacillus present. A combined vaccine was made and given with little result.

On January 3, 1916, the antral openings were enlarged and curetted, and both sphenoid cavities were curetted again.

On January 15, 1916, both frontal sinus openings were again enlarged.

On March 20, 1916, on account of the persistence of the discharge from the right antrum a radical operation was resorted to.

On March 22, 1916, the patient complained of severe pain in the right side of the abdomen and on March 24 an appendectomy for suppurative appendicitis was performed, a smear from the appendix showed a streptococcus, a staphylococcus, and the colon bacillus present. Ten days after the appendix was removed, patient complained of pain in both ears. A 10 per cent. ichthyol solution in glycerin was instilled in both ears with no results. Twenty-four hours later both ear drums were incised, with a complete amelioration of the symptoms in the left ear. The pain continued in the right ear and suppurative mastoiditis developed.

On account of the weakened condition of patient, I was inclined to temporize with this new surgical condition. On April 10 the symptoms became so urgent the mastoid was opened under cocaine anesthesia and later ether was resorted to. A total eradication of the mastoid cells was performed and the lateral sinus was laid bare as there existed a perisinus abscess. A smear from the opened mastoid showed a streptococcus and a staphylococcus. A combined vaccine was made and the patient improved under this treatment.

Ten days after the mastoidectomy the patient was discharged from hospital.

The blood examination showed at this time the following: Hemoglobin, 80 per cent.; red corpuscles, 4,000,000; white corpuscles, 9,000; polymorphonuclears, 68 per cent.; small lymphocytes, 24 per cent.; large lymphocytes, 7 per cent.; eosinophiles, 1 per cent.

An examination of patient at present time (June 20, 1916), shows her to have gained much in weight. The sinuses have all ceased discharging with the exception of the right frontal sinus, which at times discharges a thin mucoid substance. The patient has had no fever for the past four weeks and is about to resume her former duties.

24 EAST FORTY-EIGHTH STREET.

Medicolegal Notes.

Competency of Physician's Testimony. — After filing objections to the probate of the scrip purporting to be the last will of his wife, the objecting husband died, and the executor of the deceased husband, who was made a party, offered to prove by the physician who attended the testatrix immediately prior to her death that at the time she executed her will she lacked testamentary capacity. New York Code Civ. Proc. § 836, relating to waiver of the privilege of a physician by enumerated persons, declares that any other party in interest may waive such privilege. The Surrogate's Court, King's County, held that the executor of the deceased husband was a party in interest, entitled to waive such privilege, for the probating of the will would affect the husband's estate, and so the testimony of the physician was competent. In re Mele's Estate, 157 N. Y. Supp. 67.

Liability of Private Hospitals for Negligence.—A patient voluntarily entered a private sanatorium, and after once leaving without permission returned and voluntarily consented to be removed to another ward where he would be practically a prisoner. Those in charge did not, during the process of removal, forcibly restrain the patient, though an attendant walked by his side. The patient suddenly broke away and fled from the sanatorium half-dressed. He entered a house where were a woman and two small children, so frightening the woman that as a result, the evidence tended to show, she was afflicted with neurasthenia and cystitis (!) for which she sued the proprietor of the sanatorium. The Wisconsin Supreme Court held that the evidence did not show negligence on the part of the proprietor, and that the plaintiff could not recover.—Torrey v. Riverhouse Sanitarium, 157 N. W. 552.

Verification License to Practise.—The Texas Court of Criminal Appeals holds that a license issued to a physician by a member of a medical examining board in 1892, certifying that the physician had been examined by such member of the board, and was thereby licensed to practise medicine and surgery until the next regular meeting of the board, showed on its face that it was a mere temporary license, good only until the next regular meeting of the board, and under no circumstances could be considered the verification license required to be filed under the present law, Acts 30th Leg. c. 123, regulating the practice of medicine in Texas. That statute has been held constitutional by the United States Supreme Court and many times by the State courts.—Gay v. State, 184 S. W. 200.

New York, October 7, 1916.

PATHOLOGICAL ANATOMY OF UNDULANT FEVER.

THE symptomatology of this affection is extremely varied, and our knowledge of the pathological anatomy correspondingly scanty. The low mortality (in medium cases) is doubtless responsible for lack of interest in this subject. Each case should therefore be subjected to close scrutiny during life and every fatality should lead to a careful autopsy. In *La Riforma Medica* of June 26, Lunghetti reports a fatal case, in part as follows: The patient, a man of forty-four, had been ill for about a month, the chief symptoms having been fever and abdominal pain. Interned in the University Hospital, Sienna, he began to show prostration with attacks of vomiting and later became stuporous. An erythema, hemorrhagic, appeared on the face. Examination of the thorax and abdomen gave negative results. The heart's action was feeble, pulse small and frequent. The Widal test was negative. Lumbar puncture showed slightly increased tension. The patient's condition became progressively aggravated, and the pulse rate was increased to 180. The mental state likewise became worse. At no time was there any elevation of temperature. The precise method of death is not stated. Autopsy begun 30 hours after death showed a very emaciated cadaver in incipient putrefaction. There was slight congestion of both brain and meninges. The abdominal contents appeared to be normal. There was slight dilatation of the heart, especially of the right side. There was some induration of the myocardium. The lungs were the seat of pronounced edema. The spleen weighed 200 grams and had a reddish brown pulp. The liver weighed 1550 grams and presented incipient fatty degeneration. All the other viscera were without alteration. The gastrointestinal canal with exception of the colon showed a slight catarrh and the mesenteric lymphnodes were tumefied. Peyer's patches were swollen, pale, and softened.

In order to exclude the possibility of a typhoid or paratyphoid infection, a careful bacteriological study of the intestinal contents was made, but only the normal bacterial flora was present therein. The *Micrococcus melitensis* was, however, after some difficulty, cultivated from the splenic pulp. The cultures were agglutinated in the blood serum, 1 to 200, but not by control fluids of various kinds. Microscopic studies of tissues involved could hardly be termed sufficient for an autopsy diagnosis. Much time was devoted to Peyer's patches, the mesenteric lymphnodes, the remains of the thymus, and the spleen. Other organs investigated were the liver and kidneys. The micrococcus was found in the intestinal wall and mesenteric lymphnodes. It is conceivable that in the course of its absorption by the intestine the coccus caused local alterations and that once in the circulation it produced those alterations in the viscera which have caused the disease to be termed a form of septicemia. Marked changes were noted in the central portion of the mesenteric nodule where the tissues were constituted of elements of the most variable nature. In most of the cells the nuclei would no longer take their proper stain and the protoplasm was opaque, granular, and disintegrated. Between the individual elements was much detritus, including fragments of red corpuscles. In certain areas these were all the evidences of recent necrosis.

The finds in the spleen and viscera in general, while inconclusive enough, may be brought into definite relationship with those of other recent investigations and with the view that Malta fever is a form of septicemia. Not so many years ago Manson stated that the pathological anatomy of the disease could be summed up by "tumefaction of the spleen." Occasional local phenomena, as well as the various dominant symptoms, resemble those seen in various well-know severe infections. This is borne out by the cerebral symptoms, the hemorrhagic rash, the intestinal symptoms, the severe and terminal intrathoracic symptoms, and involvement of abdominal viscera, all present in the author's case. Certain severe lesions of general infection, as endocarditis and nephritis, were notably absent in this case, although occasionally found by others. Malta fever occasionally masquerades as a pneumonia or other severe local affection. Taking the clinical with the autopsy finds the author would place this fever nearest to paratyphoid or to colisepsis.

MEDICAL MATTERS IN MADAGASCAR.

FROM remote corners of the world, if any place can be called remote nowadays, come reports of medical discoveries, sanitary measures, successful operations, and other bits of news which make us look forward to the time when in the darkest district of the Malay Archipelago the witch-doctor shall have been supplanted by the good old G. P. The Sultan of Sulu no longer invokes a familiar when he has the tummy-ache; he has a leucocyte count and the court physician betakes himself to his office and sharpens up his favorite scalpels. The name of Madagascar is somehow associated in our minds with long, low, rakish-looking canoes manned by ten or twenty savages, crinky kreeses dripping with blood, cannibal feasts by moonlight, and all the other sanguinary appurtenances of barbarism. It would seem, however, that in hygienic matters at least this island is fully up to date, thanks to the efforts of the late French governor, General Gallieni, whose work is described by Dr. Kermorgant in the *Revue d'Hygiène* for June.

When General Gallieni first assumed charge of the island in the early nineties he was horrified at the insanitary conditions prevailing, the fearful mortality from preventable diseases, and the low birth-rate. With an enthusiasm suggesting rather a doctor devoted to his profession than a military man he set himself to remedy these conditions. His chief work and his happiest results were along the line of infant mortality. He had native women trained as midwives and he established and popularized maternity institutions. He regulated marriage and restricted divorce. He exempted the fathers of five children or more from taxation and taxed bachelors instead. He gave prizes to the mothers of large families and organized hospitals, dispensaries, and orphanages.

In 1896 Gallieni founded a medical school for the natives which, after many vicissitudes, due largely to native prejudice, is now turning out well-trained physicians. In 1899 a Pasteur Institute was founded for the production of smallpox vaccine and the treatment of hydrophobia. Lazarettos were established for the segregation of lepers, a central pharmacy for the supervision of drugs, and information about disease and its prevention was disseminated in a popular way.

Gallieni's services, it is gratifying to record, were appreciated by his subjects as well as by his mother country. The former named him "Ray Amandreny," meaning "both father and mother," and the French Academy of Medicine awarded him a gold medal, the highest gift in its power. These labors of the general in the cause of human welfare will overshadow, in the mind of the medical profession at least, his military achievements, glorious though they undoubtedly were in the present war.

THE DAILY MORNING HEADACHE OF HYPERTENSION.

Daily morning headaches have been said to occur under a variety of conditions. In the malarial days of New York it often meant "dumb ague" and responded readily to quinine. Occurring early in the forenoon in a man in his forties it betokened the need of glasses. Waking early with a headache could mean alcoholism or uremia. There is much reason to look with scepticism on this pigeonholing arrangement. There is reason to believe, for example, that headaches "due to uremia" may often arise simply from hypertension, or conditions which cause or follow the latter.

For fifteen years Rathery kept track of morning headaches, and associated them with interstitial nephritis of scarlatinous origin, syphilis, nicotinism, and excess in protein consumption. As accessory factors he recognized sedentary occupation, excessive mental labor, and great responsibility. Renon, in an equally long observation period (*Journal de Médecine et de Chirurgie*, etc., August 25), in which Pachon's oscillometer was used, found the presence of excessively high tension. This headache may involve the entire cranium or only portions of it (it is seldom occipital). It comes on early in the morning and may waken the patient at 5 or 6 A.M. It is intense, and he does not feel like getting up. It has a maximum at 9 or 10 A. M., and may disappear at noon. The subject, unfitted for labor or even for coherent thinking, rushes for the headache powder or equivalent. He has tried them all. One gives him relief for an hour and a half, and three may keep him free during the forenoon. Meanwhile he becomes the victim of the drug and its toxic effects, until the remedy is worse than the disease. Such a man shows an enlarged left heart, accentuated second sound, and polyuria with traces of albumin. In other patients there is only a dull morning headache augmented on slight mental or physical exertion ("painful thinking"). The condition is progressive and Renon has never seen a recovery. Often death occurs with great promptitude after the diagnosis is made. Nevertheless intensive treatment will give relief.

First, the coal-tar derivatives must be shut off, as well as tobacco. Mental rest must be ordered. For a week at least the patient must go on a milk regimen as the sole diet. Then he may have milk days and live for the rest on fruits and vegetables for two weeks more. He is then placed on a light, low protein regimen for several weeks. If the blood tension has not come down, and if headache still persists, Renon advises certain harmless hypotensives, such as thiosinamine. Iodides are given only if a syphilitic basis can be shown. Otherwise they aggravate the symptoms.

A Warning.

We are obliged to call attention of our readers once more to the taking of subscriptions to the Medical Record, *The American Journal of Obstetrics and Diseases of Women and Children*, or the *British Journal of Surgery*, by unauthorized persons. There has for a long time been an organized band of these rascals working the cities and larger towns in many sections of the country. Their scheme, or one of their schemes, is to represent themselves as an association of indigent students (the latest one we have heard of calls itself the "Western Students' Benefit Association") who are given free tuition in a medical college in return for a certain number of paid subscriptions, new or old, to either or all of the above-mentioned journals. They thus work upon the sympathies of their dupes who feel they are helping deserving young men to get a medical education, while at the same time they are treating themselves to some of the best obtainable medical literature. The latest trick is to offer a physician whose subscription happens to be overdue a receipt in full for the payment of $4.25; naturally such a generous offer is accepted in many cases. We would again warn our present subscribers not to give money for renewals to any but our authorized agents, or preferably (as a forged authorization may be presented) to send it direct to the subscription department of one or the other journal. As to the intending new subscribers, we are doing our best to protect them by notifying the police of the cities where these gangs of sharpers are working. We would also suggest to our friends that they would be doing a favor not only to us, but, and especially, to their colleagues if they would speak of this matter in their society meetings, cautioning their fellow-members never to pay money for books or for subscriptions to this or any other journal to

any but authorized agents of the publishers. By giving such warning they would help the readers not only of this but of other journals, for the subscribers to several of our contemporaries have been defrauded in the same way and by the same persons.

Another Theory Exploded.

Solomon Yacovitto of Brooklyn, a lamplighter of that city and a victim of rheumatism in the legs, his vocation suffering as a result, was told by a friend that if he would bathe in water in which a certain drug had been dissolved his rheumatism would be cured and, in addition, his skin would be whitened. This wonderful drug the friend said, or so Solomon understood, was calcium carbide; so he purchased a can of this, filled his bathtub, seated himself in it, and then emptied the contents of the can into the water. Perhaps there was some mistake. At any rate, there was an explosion and a flash of flame, and Solomon instead of curing his rheumatism added severe burns to his other troubles, and so far from bleaching his skin came out of the tub much blacker than when he went in. Which all goes to show that amateur prescribing is not always successful.

News of the Week

Poliomyelitis Epidemic Decreasing.—In New York City, for the week ending September 30, 140 new cases of poliomyelitis were reported, a decrease of 14 as compared with the previous week. The total number of cases in the city to the same date was 9,029, and of deaths 2,286. So far as any serious danger to children is concerned, the health officials believe that the epidemic is now a thing of the past. The course of the epidemic since July 1 is shown by the following table, giving the number of new cases reported each week since that time:

Week ending		Week ending	
July 8	557	August 19	922
July 15	979	August 26	744
July 22	795	September 2	487
July 29	962	September 9	351
August 5	1,168	September 16	254
August 12	1,210	September 23	160

The forcible removal by the Department of Health of a nineteen-months' infant believed to be suffering from the disease, from its home in Jamaica to the Queens Borough Hospital, has caused some bitter feeling in the town, and the Civic Association of Jamaica is threatening to bring before the next Legislature an act to restrict the powers of the Board of Health.

Poliomyelitis Serum Collected.—The Harvard Medical School has recently appointed a commission, consisting of Dr. Robert W. Lovett, professor of orthopedic surgery, chairman; Dr. Milton J. Rosenau, professor of preventive medicine; and Dr. Francis W. Peabody, assistant professor of medicine, to supervise the collection of blood serum from persons who have recovered from infantile paralysis, and its distribution among physicians, in an attempt to stop the spread of the disease. The serum will be distributed to physicians free of charge.

City Death Rate Low.—For the week ending September 23, the death rate in New York City was only 11.17, as compared with 11.79 for the corresponding week of last year. The rate for the first thirty-nine weeks of the year, however, is slightly higher than that for the same period of 1915, the respective figures being 14.33 and 14.26 per 1,000 of population. The increase is due in part, of course, to the epidemic of poliomyelitis.

Sick Rate Among Troops.—Slight increases in the sick rate of the troops on the Mexican border are shown in a report made on September 25 to the War Department. For the week ending September 16 the morbidity percentage among the men of the National Guard was 2.13, as compared with 1.91 for the week preceding. Among the regular troops the rate for the same week was 2.16, against 2.15 for the preceding week. The deaths during the same time numbered five among the National Guard and two among the regulars.

Civil Service Examination.—The New York State Civil Service Commission will hold an examination on November 4 for the purpose of filling a vacancy at Sing Sing prison in the position of assistant physician, and of other vacancies as they occur. The examination is open only to men who are licensed medical practitioners in this State, and since graduation have had at least one year's experience on the resident medical staff of a general hospital. The salary is $1,500 without maintenance. Further details and application blanks may be obtained from the State Civil Service Commission, Albany, N. Y.

Association for the Study of Internal Secretions.—With the object of correlating the work of physicians and other students interested in the investigation of the internal secretions, this association was recently formed. The plans of the society include the establishment of libraries and the publication of a scientific bulletin containing a résumé of the work being done in this field. The secretary of the Association is Dr. Henry R. Harrower, Glendale, Los Angeles, Cal., who will be glad to send full details in regard to membership, etc., to those interested.

Cost of Disease.—At one of the meetings of the American Chemical Society, held last week in New York, it was stated that this country is losing close to one billion dollars a year through preventable occupational diseases, in spite of the growing movement in the direction of better working conditions. A paper by Dr. W. A. Lynott of the Federal Bureau of Mines contained statistics showing that every worker in the United States loses an average of nine days' work a year through occupational diseases that could be prevented by the use of proper machinery and through sanitation.

Health Exhibit Popular.—The New York Social Hygiene Society, which is conducting a campaign in this city for the prevention of venereal diseases, announces that between July 21 and September 20 of this year 19,390 persons visited this society's exhibit at Coney Island.

Physicians Oppose Compensation Act.—A number of physicians, representing the members of the Massachusetts State and Massachusetts Homeopathic Medical Societies, met in Worcester on September 20, and made formal protest against one section of the workmen's compensation act of that State. It was declared that the law, as it now stands, works a hardship on the workman as well as on the physician, in that it deprives the former of the right to call in a physician whom he knows—the family doctor. Plans were formulated for an active campaign before the next session of the Legislature to have the act amended.

Medical Colleges Open.—The College of Physicians and Surgeons, Columbia University, New York, opened on September 27 with a total registra-

tion of 480, the entering class numbering 142. At the opening exercises, Dr. Warfield T. Longcope, Bard professor of medicine, spoke on "Milestones in Medicine."

The thirty-seventh annual session of the College of Physicians and Surgeons of Boston began on September 20, with an enrollment said to be the largest in the history of the college.

Lectures on Mental Hygiene.—The New York City Department of Education, in conjunction with the Mental Hygiene Committee of the State Charities Aid Association, has arranged a course of six lectures on mental hygiene, to be given on Wednesday evenings during October and November, in the Young Men's Christian Association Hall at 5 West 125th Street, New York. Among the lecturers will be Dr. Stewart A. Paton of Princeton University, Dr. Ira S. Wile of New York, and Dr. William Mabon, superintendent of the Manhattan State Hospital, New York.

Yellow Fever Commission Returns.—Gen. William C. Gorgas, chairman of the commission sent out by the Rockefeller Foundation to investigate the occurrence of yellow fever in South America, returned to New York with other members of the commission on September 25. The commission has already made investigation in Chile, Peru, Bolivia, Ecuador, and Panama, and will shortly sail for Brazil to continue its investigation of the disease in that country.

Gifts to Charities.—By the will of the late Mrs. Juliet C. Percival of New York the Hahnemann Hospital of this city receives a bequest of $40,000, to be used for the establishment in the children's ward of beds in memory of the giver's son, George Sidney Percival.

A number of New York institutions are remembered in the will of the late Mr. H. B. Dick of this city. The Presbyterian Hospital receives $7,500, the Roosevelt Hospital, the Manhattan Eye and Ear Hospital, the Babies' Hospital, and St. Luke's Home, $5,000 each, and St. John's Guild $3,000 for the floating hospital.

By the will of the late Eckley Brinton Coxe, Jr., of Philadelphia, bequests are made as follows: Children's Hospital, $100,000 as an endowment, and in addition $10,000, the income of which is to provide for Christmas presents and an annual dinner for the children patients, the nurses, the servants, and members of the dispensary staff; Orthopedic Hospital and Infirmary for Nervous Diseases, $50,000; Pennsylvania Epileptic Hospital and Colony Farm, $25,000.

By the will of the late Stephen B. Colladay of Philadelphia the sum of $2,000 is bequeathed to the Samaritan Hospital.

Personals.—Dr. Bernard Glueck has been appointed physician and surgeon at Sing Sing prison, succeeding Dr. Amos O. Squire, who recently resigned. Dr. Glueck has recently been conducting the psychopathic clinic founded by Mr. John D. Rockefeller at the prison.

Dr. Murray H. Paterson of Chatham, Ontario, returned to New York on September 30 from active service in France, where he won the Military Cross for bravery under fire. On July 1, when the allied offensive began, Dr. Patterson led a party of bearers out under a heavy fire and succeeded in bringing a number of wounded soldiers safely within the lines.

The death of Dr. A. Magnan, chief of the Bureau of the Insane in Paris, and director of the French School of Advanced Research, has recently been reported.

Dr. Paul E. Bechet has removed to 40 East Forty-first Street.

Dr. Raimundo Menocal has been appointed Secretary of Sanitation in Cuba, to succeed Dr. Enrique Nuñez, who died recently in this city.

Medical Society Elections.—COLORADO STATE MEDICAL SOCIETY: Annual meeting at Glenwood Springs, in September. Officers elected: *President*, Dr. A. C. Magruder, Colorado Springs; *first vice-president*, Dr. S. B. Childs, Denver; *second vice-president*, Dr. A. L. Trout, Walsenburg; *third vice-president*, Dr. W. W. Frank, Glenwood Springs; *fourth vice-president*, Dr. A. J. Nossoman, Pagosa Springs; *delegate to the American Medical Association*, Dr. Oliver Lyons, Denver; *alternate delegate*, Dr. C. W. Plumb, Grand Junction; *councillors*, Dr. M. R. Fox, Sterling, and Dr. Samuel French, Meeker; *member of the Publication Committee*, Dr. Philip Hillkowitz, Denver. The next meeting will be held at Colorado Springs in September, 1917.

UTAH STATE MEDICAL ASSOCIATION: Annual meeting at Salt Lake City on September 12 and 13. Officers elected: *President*, Dr. Samuel C. Baldwin, Salt Lake City; *first vice-president*, Dr. Joseph R. Morrell, Ogden; *second vice-president*, Dr. P. M. Kelly, American Fork; *third vice-president*, Dr. David C. Budge, Logan; *treasurer*, Dr. T. A. Flood, Salt Lake City.

OREGON STATE MEDICAL ASSOCIATION: Forty-second annual meeting at Portland on September 14 and 15. Officers elected: *President*, Dr. R. C. Yenney, Portland; *first vice-president*, Dr. H. J. Clements, Salem; *second vice-president*, Dr. Leo Chilton, Canyon City; *secretary*, Dr. Clarence J. McCusker, Portland; *treasurer*, Dr. Katherine R. Manion, Portland.

WASHINGTON COUNTY (VT.) MEDICAL SOCIETY: Annual meeting at Northfield on September 19. Officers elected: *President*, Dr. George S. Bidwell, Waterbury; *vice-president*, Dr. Clarence H. Burr, Montpelier; *secretary-treasurer*, Dr. Harlow A. Whitney; *auditor*, Dr. De F. C. Jarvis, Barre.

NEW ENGLAND ASSOCIATION OF JEFFERSON MEDICAL COLLEGE GRADUATES: Tenth annual meeting at Farmington, Conn., on September 9. Officers elected: *President*, Dr. Eckley R. Storrs, Hartford, Conn.; *vice-president*, Dr. Albert C. Getchell, Worcester, Mass.; *secretary*, Wallace P. MacCallum, Boston; *treasurer*, Dr. Frank I. Payne, Westerly, R. I.

Obituary Notes.—Dr. JOHN WAYT POINDEXTER of Prairie Home, Mo., a graduate of the Medical College of Virginia, Richmond, in 1875, died at his home recently, aged 65 years.

Dr. EDWARD REESE FELL of Philadelphia, a graduate of the medical department of the University of Pennsylvania in the class of 1861, and assistant surgeon in the United States Army during the Civil War, died at his home on September 15, at the age of 77 years.

Dr. THOMAS A. C. KEPHART of Altoona, Pa., 47 years old, was killed in an automobile accident on September 18. He was graduated from the University of Pittsburgh School of Medicine in the class of 1912.

Dr. FRANK WEBSTER of Dayton, Ohio, a graduate of the Pulte Medical College, Cincinnati, Ohio, in 1882, died on September 21, aged 62 years.

Dr. JOHN H. WILSON of Bethlehem, Pa., a graduate of the University of Pennsylvania, School of Medicine, Philadelphia, in 1860, and a member of

the American Medical Association, the Medical Society of the State of Pennsylvania, and the Northampton County Medical Society, died at his home on September 12, after a long illness, aged 81 years.

Dr. SANFORD HANSCOM of Somerville, Mass., a graduate of the Medical School of Harvard University, Boston, in 1868, and a member of the American Medical Association, the Massachusetts Medical Society, and the Middlesex South District Medical Society, died at his home on September 20, aged 75 years. Dr. Hanscom was a veteran of the Civil War.

Dr. THOMAS FITZGIBBON of Milwaukee, Wis., a graduate of Rush Medical College, Chicago, in 1882, a member of the American Medical Association, the State Medical Society of Wisconsin, and the Milwaukee County Medical Society, and formerly professor of gynecology in Marquette University Medical Department, Milwaukee, died at his home in St. Francis on September 17, after a long illness, aged 62 years.

Dr. RICHARD MOTT MOORE of Rochester, N. Y., a graduate of the University of Buffalo, Medical Department, Buffalo, N. Y., in 1878, died at his home on September 13, aged 59 years. Dr. Moore was a member of the American Medical Association, the Medical Society of the State of New York, the Monroe County Medical Society, the Rochester Academy of Medicine, the Rochester Academy of Science, the Board of Health of Rochester, the Monroe County Milk Commission, and was physician to the Rochester General Hospital.

Dr. JOHN LESTER KEEP of Brooklyn, N. Y., a graduate of the Hahnemann Medical College and Hospital of Philadelphia, in 1860, and of the New York Homeopathic Medical College and Flower Hospital, New York, in 1866, consulting physician to the Cumberland Street Hospital, a member of the American Institute of Homeopathy, the Brooklyn Medical Society, and the Associated Physicians of Long Island, and a former president of the Alumni Association of the New York Homeopathic Medical College, died at his summer home on Shelter Island, New York, on September 30, at the age of seventy-eight.

Correspondence.

THE BROAD STREET HOSPITAL.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the News column of the MEDICAL RECORD for September 30 there is an item concerning the Broad Street Hospital, in which it is stated that "the institution will serve the district south of Fulton Street which has not heretofore had a general emergency hospital." Your informant is evidently in error in respect to this matter, for the House of Relief of the New York Hospital, known as the Hudson Street Hospital, served that district for many years, and provided an ambulance service that was apparently quite adequate. During the past year a portion of the district served by the Hudson Street Hospital was given to the Volunteer Hospital, whose ambulance district includes that mentioned in the paragraph. So far as it is possible to learn from unprejudiced sources, the Volunteer Hospital is rendering complete and satisfactory general emergency service at the present time, so that the statement quoted is inaccurate as it stands.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

BRITISH ASSOCIATION—FATIGUE AMONG SOLDIERS—DECIMAL COINAGE—WEIGHTS AND MEASURES—CASES OF PLAGUE—CERTIFYING SURGEONS—COUNCIL FOR COMBATING VENEREAL DISEASES—OBITUARY.

LONDON, Sept. 15, 1916.

THE meeting of the British Association closed last week. Of its twelve sections that on Economic Science obtained a good deal of attention, as it considered the subject of fatigue among our soldiers as well as among munition workers. Dr. Hunter urged that it is time to consider decimal coinage and weights and measures if Great Britain is to hold her own after the war, for neutral countries would naturally deal with those who used those to which they were accustomed. The United States were aware of this. The French had adopted our meridian, why should we not change our weights and measures for the system adopted by every other civilized nation? We should save immensely by so doing and no other nation would try our system. The colonies would follow, and in fact only waited our lead. Professor Kirkaldy (presiding) wished it to go forth that in the view of this section, the Anglo-Saxon world should come together and try to bring about this reform. The next subject of discussion was fatigue, on which a report was presented of a committee of investigation and another by Dr. Maitland, who had special opportunities for observation during the war in Serbia. He said military necessities and the impossibility of providing reliefs, rest and uninterrupted sleep prevent an army getting the utmost value out of the unit. In fact, long continued strain in the trenches resulted in cases of breakdown; these recovered after rest, but on return to the trenches broke down again and had to be discharged as of no further use. We could not hope to obtain an ideal working day for each military unit, but with the increased ability to supply reinforcements we could diminish the strain and it was most important that one should do so.

The announcement that cases of plague had occurred in England gave rise to considerable public excitement and doctors in all directions have been closely questioned about it. Three cases were reported last week at Bristol and two at Hull. The rat-flea is the carrier of the toxin to man and our seaport towns are in the chief zone of danger. The vessels carrying grain are so commonly rat-infested that they transmit plague over long distances and it is probable that the cases at Bristol and Hull were ship-borne.

Certifying surgeons have been relieved of some of the duties that have been long carried on in respect to accidents, but notice of poisoning by lead, phosphorus, arsenic or mercury has still to be sent to the inspector as must also notice of toxic jaundice and of anthrax.

The National Council for Combating Venereal Disease has issued a synopsis of its report made by Captain Douglas White. In a prefatory statement the chairman of the commission (Lord Sydenham) hopes it will be found a convenient compendium of the whole subject of this disease as elucidated by the inquiry of the commission and it seems probable that this hope may be realized. The synopsis is very well described as only "a shortened report," the shortening being effected, not by whole-

sale omissions, but by systematic abbreviations, while the economic effects of the disease are stated in full and the summary of recommendations is given verbatim. This report will be of great assistance to those who have charge of local schemes and may serve as a hand-book to their deliberations. At the first meeting of the National Council for combating the disease, Dr. Fred. Taylor, President R. C. P., explained the attitude of the profession toward this important campaign and pointed out that the National Council has for one object an inquiry into medical education in reference thereto. He remarked that medical education is a life-long occupation of the profession and suggested that it might be carried on more actively, though at present there is a shortage of clinical material in the schools which would serve the purpose. Unfortunately at some institutions there is prejudice against the admission of venereal cases, but it is hoped that this is fading and in time will be eradicated.

Lieut-Col. Wm. Selby, I.M.S., Principal of King George's Medical College, Lucknow, Hon. Surgeon to the Viceroy of India, died September 8. Born 1869, he took the double qualification 1892, proceding to F. R. C. S. Eng. in 1905. He was in the relief force in Chitral in 1895, for which he had the medal and clasp. In 1897-98 he was in the operations of the Northwest Frontier of India and in the Tirah campaign, for which he was mentioned in dispatches. He was awarded the companionship of D. S. O.

CANADIAN LETTER.

(From Our Special Correspondent.)

ONTARIO MEDICAL ASSOCIATION—PERMANENT DISABILITY OF INVALIDED SOLDIERS—ELECTION OF OFFICERS—CONFERENCE OF HEALTH OFFICERS OF ONTARIO—MILITARY HOSPITALS' COMMISSION—POLIOMYELITIS—OBITUARIES.

TORONTO, September 30, 1916.

ALTHOUGH now somewhat ancient history, it may be said, more especially as little notice has been taken of the matter in American medical journals, that the meeting of the Ontario Association, which was held at the end of May last, was one of the most successful from all standpoints ever held. Several causes combined to bring about this result. The annual meetings of the Canadian Medical Association which should have taken place in 1915 and 1916 have been postponed and consequently the lack of exchange of views and opinions, rendered possible to a large extent only by such meetings, was felt by members of the Canadian medical profession. Moreover, the war in Europe had supplied an abundance of military and surgical topics of which full advantage was taken. Dr. H. B. Anderson of Toronto, the president, delivered an able address to which it would be impossible to give due credit within the limits of a letter. Sir James Grant, the nestor of medicine in Canada, in the course of an appreciation of the address paid an eloquent tribute to the splendid work being done both at the front and at home by Canadian medical men and nurses. It will not be out of place when mentioning Sir James Grant to call attention to the fact that he was a pioneer in the employment of serum therapy. Recently in *American Medicine* he described his work in this direction which has now been generally recognized throughout Canada.

The Hon. Senator J. C. McLennan, M.D., gave an address on "Problems and Plans of the Military Hospitals' Commission in Dealing with Invalid Soldiers." Among other facts that Dr. McLennan stated was that out of 200,000 soldiers who had gone from Canada, only six had returned totally blind and only five wholly unable to work. Tuberculosis had not been nearly so prevalent among Canadian soldiers as had been anticipated. The military commission had provided for 1,700 consumptive men, but the hospitals had never been more than two-thirds full.

At the business session Dr. A. Dalton Smith of Mitchell was elected president for the ensuing year, and Toronto was decided upon as the place of meeting. The other officers elected were: *Vice-President*, Dr. C. L. Starr, Toronto; *Treasurer*, Dr. J. H. Elliott, Toronto; *Secretary*, Dr. R. A. Clarkson, Toronto; *Representatives to the Canadian Medical Association*, Dr. H. B. Anderson, Dr. H. J. Hamilton of Toronto and Dr. G. S. Cameron of Peterborough; *Executive Committee*, Dr J. D. Wishart of Toronto and Dr. F. C. Neal of Peterborough.

The fifth annual conference of the health officers of Ontario was held at the University of Toronto, on the last two days of May. Dr. A. J. Macauley, medical officer of health of Brockville, vice-president, presided in the absence of the president, Dr. Macpherson of Peterborough, who was on active service. Of the many instructive discussions given none was of greater interest than a lecture upon sanitation in Serbia given by Major W. D. Sharpe who served as surgeon with the British Naval Hospital in Belgrade in the first year of the war. The next meeting will be held in Toronto. The officers elected were: Dr. A. J. Macauley, president; Dr. T. W. Vardon, vice-president; Dr. J. W. S. McCullough, secretary.

A year ago the Military Hospitals' Commission of Canada was appointed and since its inauguration there have sprung into being no fewer than 22 military convalescent hospitals. The convalescent hospital in the building formerly used as Bishop Strachan's girl school in College Street, Toronto, is certainly the best equipped in Canada and probably as well equipped as any military hospital in the world. It contains mechanical means for treating injuries and conditions of every description, under the charge of Mr. F. Davies, who is experienced and skilled in the employment of such modes of treatment. I shall have occasion to refer to the convalescent hospital and to the excellent work of Mr. Davies in greater detail in a future letter. It has been suggested, and the suggestion seems worthy of consideration, that a series of military hospitals should be established throughout Canada, not for convalescents who have already received abroad such surgical treatment as their condition called for, but for soldiers, who while they will be unfit for further active service, are yet capable of making the sea voyage to Canada to receive surgical treatment at the hands of Canadian surgeons. This procedure would tend to relieve the already overtaxed capacities of British hospitals and would also possess the advantage of bringing the men back to home and friends sooner.

Col. Herbert Bruce of Toronto, who has just been made a full colonel in the Canadian Army Medical Corps, has received a commission to inspect all the Canadian hospitals and medical institutions to which the Canadian Government is contributing, to report upon their work, and to offer any recommendations in regard to the same which he may

think fit. According to the lay papers Colonel Bruce has inspected the hospitals and institutions in Great Britain, has criticized some features of their management, and has made certain recommendations. He will afterward proceed to France to inspect the various base and stationary hospitals, casualty clearing stations, and field ambulances, and will then visit Salonica. Colonel Hodgetts, head of the Canadian Red Cross in England, has announced the intention of the society to establish another hospital of 1,000 beds, probably on the Kentish coast.

Poliomyelitis is more or less rife in different parts of Ontario. Toronto has been comparatively free, in fact there have been only one or two isolated cases. In Hamilton the epidemic was somewhat serious. However, every precaution was taken by the officers of health to prevent the spread of the disease. Dr. Charles Hastings, M.H.O., of Toronto, has stated recently that despite the excessive heat and continued drouth of the past summer, the death rate of Toronto has been lower than in 1915. This is especially true of diseases of children.

Prof. Thomas Gregor Brodie, F.R.S., who was associated with Prof. A. B. Macallum in the department of physiology at the University of Toronto since 1908, died suddenly in London, England, on August 20. Dr. Brodie was born in Northampton, in 1866, and was educated at Cambridge and London. He had held several important appointments in England, including that of director of the Research Laboratories of the Royal College of Physicians and Surgeons. Dr. Brodie had done some important original work in the sphere of physiology.

Dr. Harry Goodsir MacKid of Calgary, one of the best known medical practitioners in the northwest of Canada, died suddenly at his home in Calgary on Aug. 17.

Capt. D. Watterson, C.A.M.C., of Montreal was killed recently in action in France.

4. What Recent Investigations Have Shown to be the Relation Between Mental Defect and Crime. A. Warren Stearns.
5. Epilepsy. Everett Flood.
6. Idiosyncrasy to Cow's Milk: It's Relation to Anaphylaxis. Fritz B. Talbot.

1. The Rat and Infantile Paralysis: A Theory.—Mark W. Richardson, who was intimately concerned in the investigation of infantile paralysis from 1909 to 1914 as secretary of the Massachusetts State Board of Health, calls attention to facts that are against the transfer of infantile paralysis by direct or indirect human contact and presents those supporting the theory that the disease is transferred by rodents, insects, or both. Militating against the transfer of the disease by personal contact, direct or indirect, are the summer incidence of infantile paralysis; the maximum prevalence of the disease in country districts, where personal contact is least intimate at all times; failure to spread in general hospitals; extreme rarity of the disease in doctors, nurses, and other attendants; entire absence of infection in laboratory workers with the virus of infantile paralysis; comparatively rare occurrence of more than one case of the disease in large families of children; the cessation of epidemics in mid-career, so to speak, before the human material has been exhausted and the opportunities for direct or indirect contact are at their maximum; the long-continued immunity of cities and towns in close commercial relations with infected centers, even though interchange of population is marked; the observation that the disease travels radially from centers of infection, and that it is very common to find the later cases on the outskirts of the infected area, and finally the practical immunity of severely infected districts for a considerable period of years in spite of the fact that new material is constantly being furnished. Facts supporting the theory that the rat and its parasite, the flea, are the principal agents in the spread of infantile paralysis are that the rat has a world-wide distribution and is found in the habitations of all classes of the community; in the winter time it keeps largely to its hole coming forth with the advent of warm weather; it is highly probable that the rat is more common in the country than in the city; the great increase in poliomyelitis during the past twenty-five years may be explained by the increase in facility of transportation; the distribution of the disease near railroads may be due to the rat-infected cars and the dropping of rats from freight cars. In the study of the epidemiology of infantile paralysis it has been a common observation that the disease occurs in foci, cases spread more or less radially, the intensity of the infection rises in one neighborhood, while it is decreasing in a focus in the immediate vicinity. These facts are hard to explain through human transmission, which would result in irregular distribution of cases. In the transfer of the infection from the rat to man the agency of the flea is assumed, although the possible contamination of food by rodent excretions might well be considered. The insect transfer may be simply mechanical or it may require a preliminary cycle of development of the virus in the flea. Furthermore, the possible rôle of cats, dogs, and other animals, or even human beings, as carriers of infected fleas, would be apparent. In grossly unsanitary surroundings the fleas might carry the infection from one child to another directly.

3. The Major Divisions of Mental Hygiene—Public, Social, Individual.—E. E. Southard, after analyzing a group of over 2,000 admissions to the Psychopathic Hospital, finds that many of the considerations in mental hygiene may be grouped under three headings. There is a mental hygiene of a public or governmental nature; a mental hygiene of a social nature, and the far more familiar and well-known mental hygiene which considers the individual as such. A certain large proportion of the cases are routine cases, whose public, social and individual features are obvious and clear, immediately suggesting an appropriate disposition and appropriate measures of treatment. They may not be successfully treated from the standpoint of the individual, but from the standpoint of society and the public authorities; they may be successfully handled on the basis of familiar and well-understood rules of government, society, and medicine. There are a minority of cases which may be called the *intensive* group, as cases of mental complications of pregnancy or of brain syphilis, requiring special treatment. There is a small but perturbing group of *public service* cases, in which one may have to deal with a family dispute with respect to will making and the like, with superior court cases given over for medical examination and decision, or with cases from the police or juvenile courts. There is in addition what may be called a *social service* group of cases in which the legal problems are not prominent, but in which economic, domestic, and other environ-

mental difficulties predominate. Finally, there are a great number of individual cases which do not belong exclusively to any of these groups. The writer points out that the mental hygienist usually starts out with the problem of improving the outlook of the individual, while lawyers, judges, and many probation officers need go a long way before they will arrive at what medical men would regard as a proper individualization of the material. He discusses the important functions of the social workers, who form the intermediary body between all the various agencies, carrying the decision of the physician to the lawyer, and the decision of both to the family, and carrying back news from the individual to the family, from the family to the judge, to the probation officer, to the physician, and to the public institution administrator. Development of the public branch of mental hygiene is in the hands of the lawyers and the institution administrator, upon whose experience, judicial decisions, and statutory provisions will gradually develop the power of society over the psychopath and his family.

6. Idiosyncrasy to Cow's Milk: Its Relation to Anaphylaxis.—Fritz B. Talbot reports two cases of pronounced idiosyncrasy to cow's milk occurring in breast-fed infants. He discusses the phenomena of anaphylaxis and points out that in certain instances it is necessary to so space the doses of the foreign protein as to sensitize and not immunize the individual. Just as when a laboratory animal has its dose of foreign protein given it at stated intervals during the process of sensitization, so much the foreign protein (in the case of the baby, cow's milk) be given the infant. This might happen when a baby was given a bottle of cow's milk only once in ten days. In other instances the first cow's milk, and all subsequent bottles, that are given the baby are vomited immediately, in which case it may be assumed that the sensitization was hereditary and present at birth. Foreign proteins may pass through the intestinal wall of infants shortly after birth, and in later infancy, when the mucous membranes are injured. Idiosyncrasy to cow's milk can be demonstrated, at least in some instances, by a specific skin test. The treatment consists in giving the infant milk from another species of animal, preferably that of the goat; goats' milk was well taken by the infants in the cases reported.

1. The Psychology of Diseases of the Respiratory Tract.—G. Hudson-Makuen emphasizes the importance of a recognition of the interdependence of specialties in medicine and of the broad general principles which should underly all specialism in medicine and states that the specialties upon which laryngology chiefly depends for its future progress and development are those of psychology and neurology. In no other specialty of medicine is the psychical element so great a factor in the causation, not only of functional, but of organic disorders as well as in laryngology. It must not be overlooked that faulty methods of breathing, vocalization, and articulation, although at first of psychical origin, frequently result in organic diseases which cannot be differentiated from diseases having purely physical bases. Many a tonsil has been sacrificed and many a turbinate bone for no other reason than that the patient is suffering from some purely psychical disability, and the sooner this fact is fully realized by the laryngologist and the rhinologist, the better it will be for all concerned. It is not enough, either in acute or chronic cases, to do operations for the correction of disturbed functions without at the same time studying the psychological aspect of the case and immediately thereafter doing something in an educational way to correct the faulty habits which accompany, either as cause or result, the condition to be modified or cured. The same principle applies to the disorders of speech. Education and re-education should always be used in addition to the necessary medical and surgical measures for the relief of disturbed respiratory phonatory and articulatory functions. The new psychology teaches not merely how to treat diseases of the special organs, but how to treat the patient himself or the reactions of the patient to these particular diseases.

2. The Hospital Treatment of Simple Chorea.—Pearce Bailey relates his experience with the hospital treatment of forty-eight cases of simple chorea. The treatment consisted in rest in bed and isolation, no communication with other patients or visitors being permitted. In certain cases cold packs were given, and in the presence of rheumatic history, and even without it, rheumatic remedies, especially aspirin, were prescribed. In a few violent cases lumbar puncture was resorted to. It was found wiser, whenever possible, to insist on three or four weeks' treatment for the purpose of re-establishing the tone of the nervous system. From his experience with these cases the writer is inclined to believe that relapses are rare among cases treated in a hospital by rest and seclusion.

3. Infective Pulmonary Endarteritis Occurring with Patent Ductus Arteriosus.—Morris Manges reports this case because of the rarity of ineffective pulmonary endarteritis, this being only the fourteenth case which has been reported or observed of which he has been able to learn. The occurrence of patent ductus arteriosus and infective endarteritis is very rare. Although the case did not come to autopsy, the clinical features agree in nearly all ways with the case reported by Hamilton and Abbott. The striking feature in this case was the mild course of the disease over a long period of observation. It was only when the patient had a rise of temperature to 104° F., and also when she had a pulmonary infarct that she was willing to consider herself sick. That infective pulmonary endarteritis should occur in congenital cardiac lesions is by no means astonishing, as the conditions which favor bacterial infection are identical with those that exist in the hearts and vessels in acquired endocarditis and endarteritis. The low grade of fever in this case and the low blood count serves to emphasize the importaance of the rule which is followed at Mount Sinai Hospital to take blood cultures of all cardiac patients who have even low temperatures. A number of cases of infective endocarditis have thus been discovered where the clinical course would not have led to a suspicion of its existence. There were no cardiac symptoms previous to the patient's illness and she had borne two children without the manifestation of any cardiac symptoms. Four additional cases are cited to show how erroneous is the view that the diagnosis of congenital cardiac disease is improbable unless there are more or less cyanosis, dyspnea and clubbed fingers, as

well as a history which goes back to early childhood. When the congenital lesions exist singly, without other complicating congenital defect, very few circulatory symptoms are present, the only evidence of them being the physical signs. This patient brings up another point which is also true of two other cases of patent ductus arteriosus referred to by the essayist, and that is the ease with which these women bore children. What is true of these women with congenital cardiac disease is also true of acquired cardiac disease. There is only one condition which gives trouble, and that is uncomplicated mitral stenosis. This view with reference to cardiac women refers to hospital patients. In private practice it is different. The prevailing views of the profession do not encourage such women to marry or have children. The poor patients, whose lives have not been made miserable by the chance of finding a murmur and whose compensated hearts have not been so needlessly and harmfully disturbed and coddled by over-solicitous physicians, usually fare better than their rich sisters. The writer does not wish his remarks to be misunderstood as too sweeping, but urges that compensated hearts should be regarded in a much more favorable light as regards marriage and pregnancy than is now the rule.

9. **Bothriocephalus Latus Infestation.**—A. I. Rubenstone reports this case which illustrates the futility of attempting to diagnose vague clinical manifestations without the aid of laboratory study. The treatment employed consisted in starvation for twenty-four hours, during which only weak tea or water was allowed. The patient then received the following prescription: Oleoresin of aspidium 45 minims, tincture of fanilla 45 minims, powdered acacia half a dram, and water enough to make one ounce. This was followed one hour later by fractional doses of calomel, one-half grain each, until three grains were administered. About eight hours later the patient sent a mass of tapeworm into the laboratory. Four fish tapeworms were entangled, varying in length from three feet six inches to five feet four inches. In a case recently reported castor oil was administered before and after aspidium and it was stated that the patient was severely ill after the treatment. This may be explained on the ground that the oil caused the absorption of some of the male fern. Oils increase the absorbability of filix-mas, and thus may lead to acute constitutional disturbances.

9. **The Paralysis of Poliomyelitis: Its Treatment in the Early Stages.**—H. B. Thomas calls special attention to the advantages of less vigorous and more closely supervised treatment in the case of weak muscles. He agrees with Lovett and others who have pointed out that the greatest danger to the convalescing infantile case is fatigue of the weak or paralyzed muscles. These weak and paralyzed muscles are sick muscles, with deranged nerve and blood supply, and should be treated as such. Sick muscles tire easily, not only by active use, but also by passive use and massage, and when they tire they are less likely to functionate the following day. Their ultimate usefulness is also harmed. In each case a study should be made of the result following treatment. It is better to undertreat rather than to overtreat. Fatigue should be avoided.

10. **A Child Weighing Twenty-five Pounds at Birth.**—D. P. Belcher reports this case and states that a search of the literature shows that of all the cases cited in which the weight of the infant was unusual it has been less than in this instance. This case is remarkable because it was a girl child, and the maternal measurements, taken after delivery, were not abnormal save for circumference at the hips, which is rather large. The baby was stillborn, but perfectly formed. It was born without mechanical assistance and caused but slight perineal laceration. The greatest difficulty was encountered in the delivery of the shoulders. The measurement across the shoulders was 12 inches and the length 28 inches. The nearest approach to these measurements found in the literature occurred in a case reported by Ortega, in which the measurement across the shoulders was 7½ inches, the length 27 inches and the weight of the child 24.8 pounds.

11. **The Cautery Treatment of Jacksonian Epilepsy.**—Frederick A. Rhodes reports a case of Jacksonian epilepsy, giving a history of having been injured twice in the right motor area. The motor area was removed by cautery with such satisfactory results that the writer has continued its use in other cases with equally good results. He finds removal of the motor area by the cautery much more satisfactory than by the knife as it is followed by less bleeding and there is less possibility of as many adhesions. There is little doubt that the motor area of the opposite side takes on the functions of the destroyed area. The operation should produce a paralysis of the affected part by which one knows that he has been successful in cauterizing the right area. This paralysis disappears rapidly after the first week.

2. The Diagnosis of Enteric Fevers in Inoculated Individuals by the Agglutinin Reaction.—Georges Dreyer and E. W. Ainley Walker state that in a certain number even of the mildest cases of these infections the rise and subsequent fall in the agglutinin titre are so definite that the diagnosis could never be in doubt. In other cases the rise and fall of the curve are much less marked and differences of opinion may exist as to whether the case is one of active infection or not. In order to assist in the elucidation of such cases the following points are of importance in the interpretation of the agglutinin curves: 1. The maximum agglutinin titre of active typhoid or paratyphoid infection occurs between the sixteenth and twenty-fourth day of the disease, and most frequently about the eighteenth to twentieth day. 2. If the maximum is reached at what appears to be an earlier date, it is important to institute a careful inquiry into the actual date of onset of the illness. 3. If it is clear that the maximum falls markedly outside the limits given above (day 16-24) a diagnosis of typhoid or paratyphoid fever should not be based on a rise in titre of only moderate extent—*i.e.* a 100 or 200 per cent. increase in agglutinin titre. Because experience is not at present sufficient to exclude the possibility that a rise of this extent may be due to other ferbrile conditions. 4. In following out the titration of the patient's serum on several successive occasions it will frequently be found that the maximum has fallen between two dates of observations. And two successive observations at about the same level do not mean that the curve is stationary at this point, but merely that the maximum has occurred between there. Similarly, if the two highest observations are at different levels, it does not follow that the highest titre observed represents the maximum of the agglutinin curve. But it does follow that the maximum has occurred between these points. 5. In inoculated persons among whom mild and atypical attacks of typhoid (or paratyphoid) fever are likely to occur with fever of perhaps only a few days' duration, and with few if any of the usual symptoms, the diagnosis of typhoid or paratyphoid fever must not be rejected without the most careful consideration. As far as experience at present goes, if a regular rise and subsequent fall, even of only 100 or 200 per cent., occurs in the typhoid (or paratyphoid) agglutinin titre of the serum, and its maximum clearly falls between the sixteenth and twenty-fourth day from the onset of illness, the case is likely to be one of typhoid (or paratyphoid) infection.

6. The Heart and Active Service.—H. J. Seeuwen has treated some 60 per cent of the most serious cases of heart trouble in convalescent soldiers by a combination of physical training and electricity. All these men were given daily open-air exercise by Major McKenzie's method, which includes gymnastic training and route marches. The light training includes slow movements of limbs and trunk and some deep breathing exercises; the full training consists of more vigorous movements and of running and jumping. For the route marches there is a light one, a walk at easy pace for about two miles, and the full route march, which is a sharp walk in quick time for from one-half to one hour. The electrical treatment consists of a daily faradization with a light current of long wired coil over the thyroid gland and heart. This treatment is often used on the continent for exophthalmic goiter. It consists in an application with two-inch botton electrodes for three or four minutes on the thyroid, followed by three or four minutes with one electrode over the heart region, the other in the neck. Deep applications of *x*-ray on the thyroid gland may also be very useful, and especially on those men with hypertrophied thyroid (25 per cent. out of the total). Tachycardia, excessive sweating, and nervous uneasiness, are the symptoms which are the most quickly and completely removed. The results obtained after an average of two months' treatment were as follows: Of the 60 men, 14 were quite fit and returned to their unit; four others are fit and will return soon; others are on full physical training and will be fit for return in a short time; over a third, or 35 per cent., will be able to return to the firing line. From 10 to 15 per cent. have to be discharged; the other 50 per cent. have improved and may be able for home service.

7. The Use of Picric Acid in War Surgery.—T. F. Brown treated 3,000 cases during the Gallipoli campaign with picric acid, since learning that this agent is four times more potent than carbolic acid in bactericidal properties. The routine treatment consists in the application to superficial wounds of 1 per cent. picric acid solution applied on thin gauze. The wound is thus left practically exposed to the air. Usually one dressing a day was sufficient. Suppurating sinuses were syringed with 0.5 to 1 per cent. of the solution twice daily, and hydrogen peroxide solution was used every two or three days to remove the débris. Arm and leg baths of a 0.5 per cent. solution for thirty minutes were used for suppurating fractures and crushed tissues, with an occasional bath of hypertonic saline as a change. A 1 per cent. solution was found too strong for the delicate epithelium of new skin. The author believes that his experience justifies the opinion that picric acid solution kills bacteria without corroding effect and prevents suppuration; it stimulates granulation of the tissue; it has marked anodyne properties, eliminating the need of aspirin or morphine in most cases; it saves much time by dispensing with hot fomentations, cotton wool lint, gutta percha tissue, etc. It may be used for the sterilization of the skin in surgical cases. It shortens the convalescent period. The contraindication to its use usually cited are, first, coagulation of the tissue; this with the solutions used is so slight that it is unnoticeable and there is no evidence of retardation in healing. A second contraindication is supposed to be its poisonous effect. In the 3,000 cases treated not one showed any signs of poisoning. A third objection is the discoloration of the skin; this is persistent, but the muscles and subcutaneous tissues apparently do not stain.

1. **The Distribution of Typhoid and Paratyphoid Infections Among Enteric Fevers at Mudros.**—C. J. Martin and W. G. D. Upjohn have tested the serums of 627 patients and 151 normal persons at the large general hospital at Mudros during November and December, 1915. They give the details of the tests with varying degrees of serum dilutions. Of the 627 cases, the total number in which agglutination with one or more of the bacilli of the enteric group was observed was 464. Of these, 213 serums agglutinated *B. paratyphosus* A and gave definite evidence of paratyphoid A infection. For parallel reasons 113 might be regarded as paratyphoid B infections. The determination of the number of typhoid infections is not so simple. Though typhoid agglutinins were found in 138 cases, these were not necessarily typhoid fevers, for all but five had been inoculated. These five exceptions were placed to the credit of typhoid infection. In seven other cases *B. typhosus* was isolated from the blood or excreta either during life or after death, leaving 125 cases in which the serological observations might be interpreted either by previous inoculation or by recent infection. There were in this group a number of cases which subsequently proved to be dysentery, pneumonias, malaria, influenza, or relapsing fever, and also 35 cases of epidemic jaundice, in which observations were made because there was a widespread impression at first that the disease was associated with paratyphoid infection. After eliminative procedures had been applied it was found that the number of cases whose serum agglutinated only *B. typhosus* was 25, or 7 per cent., while 61 per cent. agglutinated paratyphoid A, and 32 per cent. paratyphoid B. If it is assumed that the distribution of typhoid fever during the whole period of the Gallipoli campaign is that which this study shows, the invalidating rate from typhoid fever represents less than one-half per cent. of the total sickness during the period. This result may presumably be attributed to antityphoid inoculation, since conditions were not unfavorable to the spread of enteric disease.

3. **The Local Treatment of Burns on a Naval Hospital Ship.**—R. J. Willan describes the plan of treatment employed in 28 cases of burns occasioned by an explosion on a naval vessel. Of these 28 cases, the burns were septic in 15. Five of the series died, four of these deaths being due to acute sepsis. The keynote in the treatment of burns is the prevention of sepsis. A burn must be regarded and treated with exactly the same care as a fresh operation wound. Further sepsis added to an already septic burn of the fourth degree and upwards, will probably kill the patient. Picric acid as a first dressing has been found to be unrivaled. For an aseptic case, equal parts of vaseline and boric ointment, plentifully spread upon white lint, makes a good, comfortable, and easily removed subsequent dressing. Immediately a burn is known to be septic hot boracic fomentations should be begun. Unless loosely applied a roller bandage put on at the first dressing will cause severe pain and it may lead to gangrene. To prevent this a new outside dressing, which is simple, efficient, comfortable, and quickly applied and changed is used. It is made of a sheet of antiseptic wool (corrosive woodwool or alembroth) with a layer of gauze on either side, folded over the burn. If it is too tight any one near can loosen the tape, which is an easy matter compared to the finding of the actual point of constriction of a too tight roller bandage.

5. **The Mechanism of Saline Dressings.**—Kenneth Taylor points out that, while the use of saline solution for dressing has come into very extensive use in England and France, there has been but little discussion of the theoretical and experimental evidence indicating its use as a dressing for wounds. In discussing what may be expected from the use of a strong saline solution in a wound, he says that by a process of osmosis water is extracted from intact cells, blood vessels, and closed lymph spaces. The same interaction increases the sodium chloride content of the intact cells and those lymph spaces which may be slowly drained. When a strong salt solution is diluted or withheld, a rapid increase of water within the cells is to be anticipated. If continued for a long period, the colloid constituents of cells imbibe water and the basis of edema is established. A small amount of dialyzable albuminous substances will emigrate from the cells, due to the absence of such substances in the dressing solution. This emigration will be unaffected by the sodium chloride concentration of the solution. By a process of diffusion an interchange of sodium chloride and water will occur between the free fluids in the intercellular spaces and cut lymph channels, which are in contact with the dressing solution, resulting in a concentration of the salt in these fluids. The sodium chloride concentration will not affect the rate of diffusion of these substances, nor will an outward current be produced by interchange of sodium chloride and water and thus carry with it the free lymph. The normally brisk reaction of secretion upon which would depend the increase in antibacterial substances may be seriously inhibited by the excess of sodium chloride in the cells. The migration of leucocytes will be checked, the tryptic digestion of sloughs suppressed, and the antibacterial substances so altered as to become inactive. The physiological saline solution is not open to these objections. Hypotonic saline solutions are likewise open to serious objections. The writer has seen hypertonic saline dressing used extensively and has not been convinced that it produces the results claimed for it. The theoretical indications for the use of salt solutions appear to be based on an untenable hypothesis of the structure of the tissues about the wound and an erroneous interpretation of physical and physiological laws. The chief beneficial character held by strong salt solution, aside from the cleansing property possessed by all watery solutions, is their mild antiseptic action.

7. **Three Cases of Bubonic Plague Arising in England.**—A. Rendle Short reports that two certain cases, and one probable, of bubonic plague have been treated at the Bristol Royal Infirmary between July 30 and Aug. 5, 1916. Two of the patients and the father of the third were workers in a rag factory in a poor part of the city. The plague bacilli have been demonstrated in a rat found in the factory and the theories that suggest themselves in regard to the source of infection are three: 1. Infection from rags, though it is said that the rags do not come from abroad. 2. Infection carried by rats escaping from ships entering the port. 3. Deliberate inoculation of city rats by an enemy. If this latter theory should be true other towns may have a visitation of rat plague, with human cases following.

La Riforma Medica.

August 16, 1916.

Kenotoxins.—Ferrannini and Fichera have been studying the fatigue toxins of the frog. They refer to the work of pioneers in this field, notably Ranke, Kronecker, Mosso and numerous others down to the time of Weichardt, who is the chief contemporary authority, and whose technique the authors have closely followed, although they selected the frog or rather one muscle of the frog, the gastrocnemius, the stimulation coming from an induced circuit with automatic closure, and the contractions recorded on a myograph. It is therefore necessary only to tire the muscle progressively and

study the numerous myograms for evidence of fatigue poisoning. In the first experiments no outside toxins are injected. The contraction waves become shorter and shorter with fatigue, but up to the last show perfect regularity, even in the so-called line of exhaustion. If a little kenotoxin is injected as the experiment begins, the influence on the myograms is shown in various ways and the line of exhaustion is reached in 4 instead of 10 minutes. The combined results are stated as follows: The presence of kenotoxin injected subcutaneously reduces notably the amplitude of the muscle contractions and augments considerably the period of latency in the same. It both shortens and renders irregular the curve of muscular fatigue, and depresses notably the excitability, contractility and force of the muscle.

History of the Study of Malaria in Rome.—Marchiafava does not go back beyond his own first studies, published in 1877. He took issue with some of the prevalent theories on the causation of melanemia. In 1879 he published accounts of studies of the blood in the spleen and bone marrow of melanemic children. One year later Laveran discovered the parasite and its power of attacking the red blood globules. For a number of years Laveran was busy with studies and demonstrations of the parasite, but it was not until 1890 that rapid methods were evolved for its prompt recognition for diagnostic ends. However, as far back as 1885 Golgi had studied the plasmodium independently both as to its morphology and its method of causing various types of disease. This scientist was the first to study Roman malaria from this viewpoint. Also, the author and Celli had been making studies along the same line and were the first to term the parasite the plasmodium malariæ. The author had really been studying the parasite since 1883, so that with Celli and Golgi he represented the beginnings of the Italian school of malaria study in distinction with the French school as founded by Laveran. Moreover, the Italians studied native malaria. Because Marchiafava really studied the parasite without knowing its nature, some would give him credit alongside of Laveran for priority, his work antedating that of the latter. However, from 1885 to 1889 notable Italian scientists opposed the author and Golgi in regard to the parasitic nature of malaria. They included Tommasi-Crudeli, Maragliano, and Mosso. In 1889 the author submitted new demonstrations of the parasite and its pathogenicity, and some years later Koch corroborated the authors' finds in connection with his work in Africa. It was now realized that different plasmodia produced different types of malaria. While Laveran is credited with discovering the plasmodium as such, Golgi receives credit for isolating the causes respectively of the tertian and quartan fevers, while the author has an undisputed claim to the discovery of the parasite of the tropical estivoautumnal fever of the Italians. At a later period the author, in addition to the parasite of the quotidian, has identified himself with the demonstration of a tertian type which predominates over all others in importance. He has received full credit for discovering the causes of the fevers of the Roman Campana. His treatise was translated into English by the Sydenham Society and he wrote the article on malaria for Wood's Twentieth Century Practice. Thus for nearly 40 years the author has been the leading Italian authority on Roman malaria.

La Presse Médicale.

August 31, 1916

Infectious Icterus with Febrile Recrudescence.—Garnier states that primary infectious icterus sometimes appears in two stages. Jaundice is at the start accompanied by fever, the latter subsiding; but before the icteric tint disappears fever recurs. It is to this type of disease that Mathieu and Weil append the term infectious icterus with febrile recrudescence. A soldier of 23 was admitted for intense icterus of a week's duration. It had begun with headache, pain in the limbs, diarrhea, and vomiting. He had been invalided for gastric disturbance. The man seemed quite ill, his countenance anxious, respiration rapid, medium febrile temperature, fever blisters on the lips, mahogany colored urine. Next day he was considerably improved, and improvement persisted, save that for a number of days icterus remained unchanged. It then began to vanish, but while still perceptible the temperature began to rise in connection with myalgia. Icterus did not increase, but its disappearance was arrested. The patient perspired profusely and felt prostrated. After six days the second febrile movement reached a crisis. The urine was absolutely free from biliary coloring matter. Fever lasted three days longer and there was a final clearing up of the icterus. There had been 32 days of jaundice, and save for seven consecutive days of apyrexia the patient had had more or less fever, which had been around 40° C., for four consecutive days in the second febrile period. Throughout, the urine was scanty. On one day it was black coffee color. A study of the urine showed that the unknown infection had caused much disturbance of the liver on both febrile periods, more marked, however, on the former. In the febrile recurrence bile pigment may be present in the feces. In a second patient the febrile recurrence came when icterus was reduced to conjunctival tints. The recrudescence may be either benign or severe. Naturally this phase presents the greatest interest. Fever appears, the urine becomes scanty, and a biliary diarrhea is sometimes seen. These occur simultaneously, and food and medication may be excluded as causes. In fact, the milk regimen generally recommended is seen to exert a favorable influence on the condition. The patients often behave like typhoid cases, and some writers have associated the two clinically, but all diagnostic tests have proved the complete absence of typhoid in these cases, 23 of which were tried out on the typhoid theory. In a few cases paratyphoid bacilli were present in the blood, as shown by agglutination tests. Despite this fact the bacterial causation of the disease is regarded as unknown. Whatever it is, it causes a biligenic reaction.

Case of Acute Yellow Atrophy of the Liver Treated by Injections of Sodium Bicarbonate; Recovery.—C. P. Longridge, Royal Army Medical Corps, relates the case of a soldier aged twenty-five who having reported ill at Gallipoli was sent to a hospital in Egypt. The symptoms pointed wholly to epidemic catarrhal jaundice, which was prevalent at that time. In a few days severe symptoms appeared, including syncope and vomiting. Icterus became marked. Liver dullness increased. Received by the rectum glucose injections, with sodium bicarbonate by the mouth. Leucin and tyrosin were present in the urine. Symptoms grew worse and delirium set in. Glucose enemata no longer practicable. Soda injected hypodermically. Patient was now unable to receive food, and urine was almost suppressed. Diagnosis of acute yellow atrophy of the liver made in consultation. The sole dependence was placed on the bicarbonate injections. One week after the patient was admitted to hospital he began to improve, the liver dullness rapidly receding. The man was discharged cured on the thirty-third day.—*Journal of the Royal Army Medical Corps.*

Book Reviews.

POLISH FOR USE IN THE CLINIC. By the Rev. FRANCIS BIMANSKI, Cook County Hospital Chaplain, Chicago: Published by the author, 1076 West Twelfth Street. Price, 5 cents; $2 per hundred.

ITALIAN FOR USE IN THE CLINIC. By the Rev. FRANCIS BIMANSKI, Cook County Hospital Chaplain. Revised edition. Chicago: Published by the author, 1076 West Twelfth Street. Price, 5 cents; $2 per hundred.

THESE are two very practical little phrase books for use in examining Polish or Italian patients. They contain lists of the simplest sort of questions in the fewest words possible, which demand no extended answers, but simply yes or no, numbers being indicated by the fingers and the location of pain or other subjective symptoms being shown by pointing. The pronunciation of the questions (which are in both English and Polish, or Italian) is indicated by a simple phonetic system in following which the physician cannot fail to make his Polish or Italian patient understand. The little pamphlets ought to be of the greatest use in the dispensaries and hospitals of every town where there is a large foreign population.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics, Materia and Diagnosis in the Jefferson Medical College, Philadelphia; Assisted by LEIGHTON F. APPLEMAN, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. Price, $6.00 per annum. Philadelphia and New York, March 1, 1916.

THIS number of Progressive Medicine contains chapters on: Surgery of the head and neck, by C. H. Frazier; Surgery of the thorax, excluding diseases of the breast, by G. P. Müller; Infectious diseases, including acute rheumatism, croupous pneumonia, and influenzia, by J. Rühral; Diseases of children, by F. M. Crandall; Rhinology and laryngology, by G. B. Wood; and Otology, by T. L. Saunders. This publication is so well known that it is not necessary to do more than draw attention to the current number.

THE PRACTICAL MEDICINE SERIES, comprising ten volumes on the Year's progress in medicine and surgery, under the general editorial charge of CHARLES L. MIX, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School. Volume I. GENERAL MEDICINE. Edited by FRANK BILLINGS, M.S., M.D. Head of the Medical Department and Dean of the Faculty of Rush Medical College, Chicago. Series 1916. Price, $1.50. Chicago: The Year Book Publishers.

AGAIN the Practical Medicine Series comes forward to help the busy practitioner, to gain the newest information in the various realms of medicine. "General Medicine" is a most satisfactory compend of the Year's literature.

MENTALLY DEFICIENT CHILDREN, Their Treatment and Training. By G. E. SHUTTLEWORTH, B.A., M.D., etc., and W. A. POTTS, M.A., M.D., etc. Fourth edition. Price, $2.50 net. Philadelphia: P. Blackiston's Son & Co. 1916.

THE fourth edition of this work is chiefly notable for the changes made necessary by the recent passage of the Mental Deficiency Acts for the British Isles, exclusive of Ireland, and the revision of the Elementary Education Act. A very interesting historical summary fills the first chapter and a rather elaborate explanation of the acts alluded to above and their applications takes up the next two chapters. Then follow the pathology, etiology, diagnosis and prognosis of the various forms of mental deficiency—two excellent chapters. A chapter has been given to the psychopathies of childhood, which is a new departure from the previous editions and which had better have been omitted or made much longer. Thus the description of dementia precox conveys little or no information. The chapter on the medical examination of defective children is good, especially the inclusion of Pasmore's "Flag" chart, but the exclusion of the Binet-Simon tests on the ground that the "space will not permit" does not seem justified. The closing chapters, devoted to the care and training of such children, are very valuable; more might have been said about sterilization, but what is said has the merit of truth. A fairly complete bibliography is appended, the book is well indexed and a number of the American institutions for the feebleminded are listed in an appendix. Altogether the work is a notable addition to the literature of the subject.

CEREBELLAR ABSCESS, Its Etiology, Pathology, Diagnosis, and Treatment, Including Anatomy and Physiology of the Cerebellum. By ISIDORE FRIESNER, M.D., Adjunct Professor of Otology and Assistant Aural Surgeon, Manhattan Eye, Ear and Throat Hospital and Post Graduate Medical School, New York, and ALFRED BRAUN, M.D., F.A.C.S., Assistant Aural Surgeon, Manhattan Eye, Ear and Throat Hospital, Adjunct Professor of Laryngology, New York Polyclinic, Adjunct Otologist, Mt. Sinai Hospital. Price, $2.50 net. New York: Paul B. Hoeber. 1916.

CEREBELLAR abscess, while a fairly common condition, is by no means readily recognized, especially in the early stages. When we consider the heavy mortality without surgical interference, amounting to nearly a 100 per cent., and the fairly good prognosis with operation, the importance of diagnosis becomes obvious. The present monograph on the subject by Drs. Friesner and Braun is excellent, both in its subject matter and style. The book, too, is attractively gotten up, illustrations are numerous, and there are many full-page plates. The first two chapters deal with the anatomy and physiology of the cerebellum. In discussing the physiology there is no attempt to be dogmatic, a clear working knowledge of the fairly well established facts only is presented in a concise way. There is a good chapter on etiology and pathology. The longest and most useful chapter is the one dealing with symptoms which is very complete, describing the methods of eliciting them, and explaining their significance. The book closes with a chapter on prognosis and treatment which is also good. A bibliography, not complete, but very extensive, is appended. There is also a good index, although this is scarcely necessary, the subject matter is so logically arranged. The book as a whole is an excellent one; neurologists and otologists should not be without it, and there is much to interest the general practitioner and the surgeon.

SKIN CANCER. By HENRY H. HAZEN, A.B., M.D., Professor of Dermatology in the medical department of Georgetown University; Professor of Dermatology in the medical department of Howard University; sometimes Assistant in Dermatology in the Johns Hopkins University; member of the American Dermatological Association. With ninety-seven text illustrations, and one colored frontispiece. Price, $4. St. Louis: C. V. Mosby Company. 1916.

A GREAT variety of tumors appear in the skin, and of these the carcinomata are the most important. They vary enormously in morphology and clinical course, from the basal-cell type which sometimes cure themselves to the melanotic tumors which are among the most serious of the neoplasms which appear in the human body. The author of this volume has prepared a very useful book in which much information concerning tumors of the skin can be readily obtained. It is provided with an excellent bibliography, the newer ideas are incorporated, and the only thing to criticize is the reproduction of the photomicrographs, which is very bad. The drawings are satisfactory and the gross photographs are fair. The book ought to furnish a valuable aid for the practitioner of dermatology or the student of dermatological pathology.

THE NATIONAL FORMULARY. Fourth Edition. By Authority of the American Pharmaceutical Association. Prepared by the Committee on National Formulary of the American Pharmaceutical Association. Official from September 1, 1916. Published by the American Pharmaceutical Association, 1916.

THE authoritative formulary, extra to the Pharmacopoeia, containing the preparations of a non-secret character which were commonly prescribed by physicians under incomplete or varying formulæ is in its fourth addition. This edition assumes its place as a legal standard and has been prepared with a view to that position. It is a remarkably exhaustive and accurate compendium of the formulæ set down and reflects great credit on its compilers. The work provides a valuable adjunct to the pharmacopoeia and of course, is a very useful book of reference, considerably more useful to the medical man, indeed, than is the other work of which this is sometimes called a companion.

Society Reports.

THE AMERICAN CLIMATOLOGICAL AND CLINICAL ASSOCIATION.

Thirty-third Annual Meeting, Held in Washington, May 9, 10 and 11, 1916.

THE PRESIDENT, DR. JAMES ALEXANDER MILLER OF NEW YORK IN THE CHAIR.

Tuesday, May 9—First Day.

President's Address.—Dr. JAMES ALEXANDER MILLER of New York gave this address on "Some Physiological Effects of Various Atmospheric Conditions." He said that atmospheric environment was an interesting and important factor in many medical problems, in which no group of physicians was more directly interested than were the members of this association, and, moreover, none in this country had contributed more than they had in the advancement of this phase of medical knowledge. It was for this reason, and also as the result of his own recent experience of three years in the work of the New York State Commission on Ventilation, that this topic had been chosen for presentation. It was his purpose to approach the subject from the physiological point of view in the hope that by a consideration of certain fundamental principles a clearer vision might be afforded to the problems involved in the effect which atmospheric conditions exert upon the comfort and efficiency of mankind, as well as the rôle they played in the causation, prevention and treatment of disease. The respiratory function of air focussed the attention of physiologists for generations. Consequently its effect upon the human body was interpreted solely in respiratory terms, and rules of hygiene were formulated upon this basis. Within doors inadequate ventilation was gaged in terms of deficient oxygen, or of excess of carbon dioxide, or later of the presence of certain volatile poisons in the air that was breathed. Out of doors, the general effect in health and disease produced by variations in climate or of its temporary representative, the weather, was also ascribed solely to their influence upon the air they breathed. To the truthful part of this hypothesis they all paid tribute in the joy of the full deep breath and upon a fine crisp morning. Certain substances in the air such as dust, bacteria and odors, were recognized as playing a part in its hygienic properties, but recent investigations appeared to demonstrate that under ordinary conditions they were not factors of sufficient importance to materially effect the health. In general it might be accepted that the chemical or bacterial content of the air within any likely degree of variation was not of material moment either hygienically or physiologically. Researches of the past decade had all led to the appreciation of the physical as opposed to the chemical feature of the air as the important physiological factor. Adequate heat regulation of the body depended largely upon the capacity for proper heat elimination which was accomplished in three principal ways which varied in their relative importance according to varying external conditions. (1) Evaporation of water from lung and skin surfaces. (2) Direct conduction by contact with a cooler medium. (3) Direct radiation to a cooler distant surface. Taking, therefore, these more important conditions together they found that the various factors reduced themselves finally to four, namely, temperature, humidity, barometric pressure and velocity of air movement. Fully as he appreciated the work of men doing for the good of the child, there had been a considerable amount of loose medical thinking upon this subject, and they were sorely in need of more scientific data based upon accurately observed clinical phenomena. Fully as he appreciated their shortcomings, he said he was not entirely in sympathy with the popular denunciation of the ventilating engineers and their artificial systems. He was convinced that by a rational system combination of open windows, a good heating plant and a proper air exhaust system when necessary, that practically any desired condition of indoor air might be obtained. The two chief faults appeared to be too high temperature and too little variation in temperature. In closing Dr. Miller made the suggestion that by breaking up into its component parts the heterogeneous mass of physical and physiological factors now included in the term "fresh air treatment" and studying the effect of each, they might be able to reach a point where the proper atmospheric conditions might be intelligently applied to the suitable case of disease and results obtained which would be far more satisfactory than at present, both from a clinical and scientific point of view.

Some Features in the Control of Typhoid Fever in New York State.—Dr. LINSLY R. WILLIAMS of Albany, N. Y., presented this communication, in which he said that the control of typhoid fever by the sanitary authorities consisted of a study of the source of infection and application of known methods of control. The most frequent sources of infection were the water supply, milk, carriers, and contact. Steady progress in improving the water supplies had caused a constant diminution in the number of cases and deaths from typhoid fever, and water-borne typhoid was now far less common than it was fifteen years ago. The reports of epidemics of typhoid fever of milk-borne origin continued. During the eighteen months ending Dec. 31, 1915, there were 111 cases of typhoid fever with 14 deaths due to milk-borne infection. Carriers played a far more important part than was formerly assumed. Until the past year practically no intensive epidemiological work was done by the New York State Department of Health, but during the past year over 20 carriers of typhoid had been detected and placed under observation and supervision. Numbers of persons still developed typhoid fever as a result of carelessness in the care of a typhoid fever patient at home. The methods of control were obvious. The water supply should be above suspicion—filtration or chlorination when necessary; the milk should be pasteurized efficiently to prevent milk-borne infection; and carriers should be determined and prevented from carrying on any work which brought them in contact with food. Acute cases should have proper care—given hospital care if possible to prevent the risk of infection to other members of the family. All persons exposed in the family should be vaccinated against the disease. All the discharges should be promptly disinfected.

Hydrology in Military Practice.—Dr. GUY HINSDALE of Hot Springs, Va., said that he had recently received a letter from Dr. Margnat of Vichy in which he described the effects of balneological treatment to the troops in the present war. In case the springs belonged to the Government, the soldiers sent for treatment were under the rules in force in military hospitals; but in other cases arrangements were made with the private owners for the use of the establishment as might be required. The mineral spring hospitals received, first, soldiers and sailors in active service; next, soldiers and sailors in non-active service, either invalidated or retired; and finally officials in the colonial or custom house or the forestry service. Cases sent for treatment were subjected to selection by army surgeons and were restricted to those in which ordinary means of treatment had been used during a sufficient length of time without success. They might, therefore, be considered chronic cases. It was interesting to note that bath trains were now used by the armies in the field. These were in use in Austria and Hungary and also in Serbia, doubtless as well in Germany and France. They were provided with a sterilizing equipment, usually a refrigerator car into which steam was introduced. When baths were required, the hot water was obtained from the locomotive. One of these trains had two cars with 30 bath tubs each, two tank cars to supply the water, one car for undressing, four freight cars with clean linen, a sleeping car for the personnel of the train, and two or three cars for the disinfection of clothing. This arrangement permitted 1200 men in the course of 10 hours to take a shower bath and have all their clothing sterilized. Even in the trenches it was possible to have needle shower baths. In the United States, as in England to-day, it would doubtless be possible to arrange for the use of privately owned spas for military purposes if it should ever become necessary.

Hereditary Hemorrhagic Telangiectasia, with Report of Two Families and a Review of those Previously Recorded.—Dr. WALTER R. STEINER of Hartford, Conn., called attention to a syndrome which presented telangiectases associatd with hemorrhages. This was first described by Legg in 1876, and was made a clinical entity by Rendu twenty years later. It was an hereditary affection, attacking both sexes equally, and being transmitted alike by both. Pathologically it had been but little investigated. The cautery was the best method of treatment for the troublesome, bleeding telangiectases. Twenty families had been recorded. An account of two additional families was reported, and in

one of them the syndrome was traced through five generations.

Abscess of the Lung Following Operation on the Tonsils and Upper Air Tract.—Dr. CHARLES W. RICHARDSON of Washington, D. C., said that in previous papers he had called attention to this serious complication. When one considered the nature of the wound left after a complete tonsillectomy, the wonder was not that serious infection took place occasionally, but that such results were comparatively rare. In conversation with workers in this field, he had had narrated to him several cases that had occurred of septic infarct of the lung with resulting abscess which had never been reported, and wherein the condition was never recognized until the resulting pulmonary abscess had formed. The reason why this complication was not more frequently reported was probably two-fold: viz., Firstly, most operators, as workers in other fields of human endeavor, prefer to report their successes, to minimize their untoward results and forget them; secondly, the serious symptoms of pulmonary infection were not always immediate, were frequently indefinite and not recognized, and the patient was discharged by the operator with the tonsillar wound healed. When the pulmonary evidence became more pronounced the internist was called into attendance, and the operator probably never heard of the untoward pulmonary complications. The causation of pulmonary abscess secondary to tonsillectomy was in all probability through embolism or infection of the lung. At the time of operation a large number of veins were opened, and these might remain patulous for several days. Septic clots or septic material might thus be carried into the lungs. After reporting several cases Dr. Richardson said that one of the objects in presenting the paper was for the purpose of again calling to the attention of the profession the fact that the performance of tonsillectomy was not the simple innocent operation that the laity and many of the internists seemed to consider it.

Appendicitis and Pulmonary Tuberculosis.—Dr. HUGH M. KINGHORN of Saranac Lake, N. Y., read this paper. He said that the facts which were presented in this communication were obtained from his cases of pulmonary tuberculosis which were treated at Saranac Lake, N. Y., by the usual open-air method from October, 1905, to December, 1914. The majority of the cases of appendicitis occurring in patients with pulmonary tuberculosis had the usual classical symptoms. During this period he treated 674 cases of well established pulmonary tuberculosis, and all were under climatic treatment at Saranac Lake. Of this number there were 393 males and 281 females. The total number of cases of appendicitis in the 674 patients was 38 5/6 per cent. Of this number, 26 were males and 12 were females. Sex seemed to play an important part, as the disease occurred in males more frequently than in females, and there was as yet no satisfactory explanation for this. Of the 25 cases that underwent operation there were two deaths, 8 per cent. All of the 25 cases seemed to act well during the operation, and there were no deaths on the operating table. The mortality of this series of 38 cases (operative and non-operative cases) was 5.2 per cent. (That was, two deaths in 38 cases.) Of the acute cases that underwent operation there was a mortality of 11.1 per cent. (1 death in 9 cases). Of the interval operations there was a mortality of 6.2 per cent. (1 death in 16 operations).

Wednesday, May 10—Second Day.

VICE-PRESIDENT PHILIP KING BROWN OF SAN FRANCISCO IN THE CHAIR.

The Diagnosis of Pulmonary Tuberculosis Without the Stethoscope.—Dr. H. LONGSTREET TAYLOR of St. Paul, Minn., read this paper. He said that the successful treatment of pulmonary tuberculosis depended primarily upon an early diagnosis. This statement had been made so often and in such a variety of ways that its repetition became trite, and yet the enormous importance of the subject made it necessary to call the attention of the profession to these old axioms again and again, and by repeated blows try to drive the nail home. The morbidity caused by tuberculosis was enormous. If recognized and untreated the morbid process advanced, and constitutional strength became more and more impaired by the progress of the disease until the prognosis was absolutely hopeless. This disease, on account of its insidious onset, deluded its victims into believing that they were not seriously ill, and did not require the services of a physician. In this class of cases, and their name was legion, the profession could in no wise be held responsible for the late diagnosis. Many patients, too, were reluctant to go to a physician lest their fears should be confirmed, and they would leave the consultation room knowing that they were victims of the great white plague. The number of unrecognized cases might be demonstrated in various ways, by autopsies of persons who had died of other diseases, or who had met violent deaths, which showed an active or healed pulmonary tuberculosis in a surprisingly large number of cases. The diagnosis of an incipient case of pulmoanry tuberculosis was an exceedingly difficult one to make if the case was truly an early one. Physical examination of such a case could reveal but little, as the signs were not pronounced and easy of detection until actual destruction of the tissues of the lung had taken place; but given a young adult with vague and indefinite indications pointing to pulmonary tuberculosis, the chances were decidedly in favor of tuberculosis being present, since it was an exceedingly common disease at this age, and the profession should not hesitate to make a tentative diagnosis of pulmonary tuberculosis subject to the result of subsequent tests. The absence of tubercle bacilli from the sputum proved absolutely nothing, and their presence in the sputum showed that an early diagnosis had not been made. It was his personal impression that the profession was too prone to rely upon the laboratory report of the sputum almost entirely in making the diagnosis of pulmonary tuberculosis to the exclusion of the clinical picture presented. Laboratory tests "with the glamour of science and the romance of novelty" could not supplant entirely the study of each individual with the sharpened observation due to long acquaintance with the danger signals thrown out by this enemy while digging himself in and preparing for a long siege, which, unless skillfully combatted, was destined to end in the fall of the individual and his unconditional surrender to the captain of the forces of death. The laboratory had proved itself of immense value to the profession, but, like everything else, was not infallible, and in the question under discussion had too often delayed a positive diagnosis, which should have been made by a careful analysis of the patient's symptoms and a painstaking exclusion of other possible conditions. The diagnosis must often be made in the absence of signs in the chest by the exclusion of other toxemic conditions that might resemble the symptoms of the tuberculosis toxemia. The cases fell into one of the following categories, with neurasthenic onset, with anemic onset, with hemorrhagic onset, onset with fever, the pleuritic onset, the pneumonia onset, the laryngeal onset, etc. The symptoms which should arouse suspicion of the presence of tuberculosis and lead to a thorough study of the case are: they had first and foremost cough, especially on arising in the morning, at which time there might be a few short coughs, with or without any expectoration. At the same time the patient might be conscious of a slight degree of debility, and the fact that he tired more readily than formerly, that he had lost little weight, and that his dyspeptic symptoms had grown more annoying. A slight fever and rapid pulse, with or without chills and sweating at night, pointed unmistakably to the necessity of thoroughly testing the patient for the presence of tuberculosis. The same was true of anemic conditions not otherwise accounted for, and of protracted convalescence from an acute disease. Many cases of tuberculosis masqueraded under the name of influenza. The object of this paper was to emphasize the fact that the profession did not give the proper value to the careful study of the patient's history, and delayed making even a provisional diagnosis until the stethoscope or the microscope revealed the condition. The lesson was that a diagnosis of pulmonary tuberculosis could be made from the patient's history and symptoms, and should be made before the chest was bared for an examination. In this way a man who was not constantly making chest examination, or the man whose hearing was defective, need not hesitate about making a provisional diagnosis of pulmonary tuberculosis. It was far better to suspect a patient of having tuberculosis who was free from it, than to give a clean bill of health to one whose chest was negative but in whose lung tubercles were developing. A period of careful observation and the use of the various tests, especially the auto-intoxication test, would soon remove all doubt.

The Advantages of Special Training in Tuberculosis in Sanatorium Surroundings.—Dr. EDWARD R. BALDWIN of Saranac Lake, N. Y., read this paper. He said that

no one would gainsay the fact that there was a steadily increasing number of physicians who were known, or called themselves, tuberculosis experts or specialists. These were usually modest individuals who generally became ill themselves and who became identified with this field of medicine. These formed by a far greater number, and they usually inhabited health resorts, or became connected with some tuberculosis institution. There had been no great enthusiasm in the past on the part of other physicians to engage in the special work of treating tuberculosis unless they were downright charlatans, like the cancer quacks, or were honest but deluded individuals who believed that they had the right "theory" of treatment or the best remedy if not the only cure. There was now a rapid change taking place owing to the well organized anti-tuberculosis movement and the rapid multiplication of dispensaries, sanatoria, and new health resorts. Public and private sanatoria were being established, and a demand had been created for trained men to take charge of them. The supply of doctors competent and willing to take up this work was being used to the utmost. The specialty of tuberculosis or phthisiotherapy was an accomplished fact. It had already been recognized as such in a few medical schools, and would doubtless be soon by many others. If gastrology, dermatology, or even proctology were entitled to recognition, no one with justice to its importance could deny tuberculosis a place on the curriculum. When an early diagnosis was made an effort was now made to get the patient into a sanatorium, for a while a least, and this was the rational thing to do. Men who lived with the patients, often themselves patients, were much better interpreters of the disease than those who had only the academic attitude to it as teachers. Even though they were most interested and enthusiastic teachers, they could not carry the weight that the man did who had personal experience with the disease or lived among those who had it. In the present undergraduate course in the best medical schools, the average student had nearly all his attention occupied, and it was too much to expect a really advanced course of instruction in tuberculosis. Very much more was being done than formerly, and very much better training for diagnosis and the management of tuberculous patients was now available, yet they did not find that it had brought about any revolution in the care of these patients by the recent graduates. It was not all the faulty or insufficient training that was responsible for this. He suspected that they took but little interest in this disease while they were in college. The disease had no real appeal to them. It appeared from many standpoints that to get a proper perspective of this disease, a special study ought to be made under the most favorable surroundings where an atmoshere of hopefulness prevailed among the physicians as well as the patients. They all knew that there was no longer the excuse for the neglected examination of the sputum, but they also knew that the time had come when the physician was called upon to find the disease before the sputum was positive, and even when there was no sputum. This meant a refinement of technique or of physical examination not yet attained by many. While the late Dr. Trudeau was still living a gentleman from Cleveland, well known for his generosity and interest in medical education, became interested in the subject through his son-in-law, who was at that time at the head of the Cleveland Tuberculosis Institute. This gentleman offered a fund to support a post-graduate school at Saranac Lake for three years, which the trustees of the Trudeau Sanatorium accepted. The experiment would be made to give a combined clinical and laboratory course in the art of diagnosis, treatment by sanatorium methods, and the organization and management of hospitals and sanatoria, both public and private. The first trial would be for six weeks. For those who contemplated city, county, or state institutional work, the Ray Brook Sanatorium would furnish facilities for study. The first session of the "Trudeau School" would be given this spring. If the experiment received encouragement, and was found to be useful to the cause, it would probably become a permanent adjunct of the sanatorium work in the Adirondacks. A Foundation for Research and Teaching to the memory of Dr. Trudeau was now being raised to further this project, and Dr. Trudeau's friends had responded loyally.

The Rôle Played by the Study of Tuberculosis in the Development of Clinical Medicine.—Dr. H. R. M. LANDIS of Philadelphia read this paper. He proposed confining his remarks to those studies which, in all truth, might be said to be epoch making. The first contribution to which he wished to call attention was that by Auenbrugger on "Percussion of the Chest." The "Inventum Novem" was first published in 1761 and forgotten for forty-seven years, when it was translated from the Latin by Corvisart, physician to the first Napoleon in 1808. It was apparent on reading the "Inventum Novum" that the major part of his observations was based on the various manifestations of this disease. Important as Auenbrugger's discovery was it became overshadowed when compared with the immortal work of Laennec. When in 1819 Laennec gave to the world the stethoscope, and his observations on mediate auscultation and the pathological anatomy of diseases of the lungs, he practically created clinical medicine as they knew it to-day. Furthermore "to Laennec will forever belong the honor of having fixed definitely the clinical picture of the disease (tuberculosis), and of having separating it by means of auscultation and his pathological studies from all similar affections of the lungs." In this instance it might be objected that the work on mediate auscultation did not represent a special study of tuberculosis. Strictly speaking, this might be true, but it was equally true that Laennec's observations were based largely on the manifestations of this one disease. The work on Mediate Auscultation should be read, he believed, by every student before his graduation. The late Dr. Austin Flint said:—"Let the student become familiar with all that is now known on this subject, and he will read the writings of Laennec with amazement that there remained so little to be altered or added." Sir William Osler had written:—"By far the ablest and most scientific of American students of the disease (tuberculosis) was Austin Flint, whose contributions to the physical signs and the symptoms were among the most important of his many clinical studies." (Tuberculosis, edited by Klebs, 1909.) To Austin Flint belonged the distinction of making the only addition to Laennec's work which could ill be dispensed with. He referred to his contribution on pitch in percussion and auscultation, a point to which Laennec paid no attention. At the present time they were passing through another revolution, namely, that which related to public sanitation. Much of the work now being done on sanitation had had its incentive in the modern crusade against tuberculosis. Housing reforms, improvements in factory conditions, supervision of the health of workers, school inspection, open air schools, and the crusades against the social diseases, infant mortality, etc., all might be traced, directly or indirectly, to the tuberculosis crusade.

Pulsating Spleen in Mitral and Tricuspid Disease.—Dr. MORRIS MANGES of New York reported this case, and reviewed the literature on this subject. In all the cases the splenic pulsation was arterial and was synchronous with the cardiac systole and increased or diminished with the vigor of the cardiac action.

Thursday, May 11—*Third Day.*

The Problem of Rest or Exercise in the Treatment of Pulmonary Tuberculosis; A Plea for Less Ergophobia.—Dr. CHARLES MINOR of Asheville, N. C., presented this communication, in which he stated that in the treatment of tuberculosis there were no more important measures than rest and exercise. Formerly tuberculosis patients were permitted to over-exercise; to-day there was a tendency to go to the other extreme. Rest was successful because it lessened circulation, and hence toxic absorption; it lessened oxidation and lowered temperature, and so decreased tissue waste; it put the diseased lung at rest, rested the heart, and lessened cough and expectoration. Furthermore, it encouraged weight gaining, and if properly managed helped to set the mind at rest. All these things were admirable, but there came a time when disadvantages showed themselves, and when a too long-continued rest ceased to be of value and became harmful. When the temperature fell so that the afternoon temperature was not over 99.4° F.; when the pulse showed a decrease of toxic absorption; when strength was improving, and when the trouble was less active and we desired to help the compensating function of the healthy portion of the lung by the quiet deep breathing that walking caused; when cough and expectoration were much reduced and we could therefore assume that there was less ulceration and activity in the diseased area; when the patient needed the stimulus of hope and the encouragement of a positive proof of his improvement; when his gain in

weight was marked and without exercise he was apt to produce fat rather than muscle, then exercise should be taken up not only on the theory of Pattison that the patient might undergo an autotuberculin treatment, but to prepare him when he should be restored to resume life in a normal way, and not to be turned, as so many were, into a pulmonary hypochondriac. Exercise might be begun with from one to five minutes, according to the case, and increased from one to five minutes a day and guarded by a carefully kept record of symptoms, fever, and pulse, kept by the patient. Exercise should be stopped or decreased just as would be done if a tuberculin reaction occurred. It was essential that the doctor see the patient at first bi-weekly, and then weekly, and never less than once in two weeks. Temperature was the best guide to detect over-exertion. If the temperature in the afternoon was as high as 99.4° F., the patient could be gotten up in the morning only, then if he progressed properly in the afternoon, and finally all day. With a temperature of 99.6° F., if the patient was restless and high strung it might often be wise to allow him up in a reclining chair for an hour or so in the morning. In cases in which persistent rest in bed failed to reduce the temperature one might at times experiment with getting the patient up, partially for the sake of mental encouragement. Unduly rapid pulse was an indication for rest, but when moderate exercise caused no rise it need not be an absolute indication for rest, but only for the reclining chair. Blood streaked or pink expectoration was an absolute contraindication to exercise, but there were some patients in whom blood streaking was a permanent habit, and in some of these cases walking had been beneficial. Any patient who was losing weight must be kept at chair rest. As to fatigue, a little healthy tire had no significance, but to get really tired was bad, whatever the temperature and pulse might be. The methods of exercise allowed were first the reclining chair and then walking, but he allowed neither a carriage nor an automobile until the patient could walk from one-half to one hour without bad effect. The automobile was easier than the carriage.

A Case of Spontaneous Pneumothorax Without Symptoms.—Dr. DAVID R. LYMAN of Wallingford, Conn., presented this paper. He stated that a case of spontaneous pneumothorax similar to those reported by Dr. Louis Hamman at the meeting of the Climatological Association, in 1914, had come under his observation. He had been so fortunate as to secure radiographic plates of the chest at the time the patient consulted him and four weeks later. At the first examination of this patient there was an apparent absence of breath sounds on the right side, the thorax being apparently normal. The patient had complained of a peculiar pain in the right side three years before. The pain disappeared and the patient did not return until a couple of weeks later, when he returned complaining of a peculiar dragging pain extending from the lower border of the right axilla upward and inward toward the mid-sternum. He had also observed a slight feeling of oppression and suffocation just back of the sternum. His family and personal history were negative. Upon examination an apparently almost complete pneumothorax of the right side was found, with complete loss of breath sounds, hypersonance, and typical coin sound. The heart was only slightly displaced and the left lung was apparently normal. He did not feel sufficiently ill to go to bed, and was only convinced of the seriousness of his condition by the aid of an *x*-ray picture of his chest. At the end of four weeks the *x*-ray examination of the chest showed that the pneumothorax had practically disappeared, save for a slight hypersonance over the base of the right axilla. However, there were signs of a latent tuberculosis. It seemed probable that the trouble three years previously was due to an unsuspected tuberculosis.

Syphilis of the Lung.—Dr. N. K. WOOD of Boston read this paper. He said that there was evidence of sufficient weight to convince the pathologist either that he was overlooking something or calling something by the wrong name. He reviewed the histories of 20 cases in which Wassermann and von Pirquet tests were made. In the cases in which these signs were negative he had radiographs taken of the chest, and the long bones of the legs. From these he was able to select seven cases that showed definite histories of lung impairment and a positive Wassermann and with negative sputum and negative von Pirquet test. To these 20 cases were added four others who did not come up to the requirements that would suggest syphilis, but which were reported because of the marked effect of mixed treatment. The writer analyzed this series of cases and pointed out the evidence which was suggestive of syphilis, such as miscarriages, still-births, early infant deaths, history of chancre, glandular enlargement, Hutchinson's teeth, or badly decayed teeth, skin eruptions, etc. He found in these patients equally strong evidence of disease of the lungs, such as marked dullness, limited excursion, poor respiration, a varying number of moist dry râles, confined more to the bases of the lungs, with a history of cough and expectoration. These cases had been under treatment for a year, simply good hygienic treatment, with tincture of nux vomica and gentian before meals and mixed treatment after meals. The results of treatment had been small gains in weight, improvement in the general physical condition, a diminished tendency to take cold, and an improvement in the chest findings. It seemed very certain that there had been disease of the lungs in these cases, and one must weigh the evidence furnished by the history as to whether it was tuberculosis or syphilis. The treatment of tuberculosis was not given, but these patients improved on tonic and antisyphilitic treatment. When the treatment was stopped they retrograded. While the evidence pointed to the existence of such a condition as syphilis of the lung, the evidence in the writer's opinion was far from conclusive. If there was such a thing as syphilis of the lung it would have to be demonstrated at the autopsy table.

Heliotherapy in Abdominal Tuberculosis.—Dr. J. H. ELLIOTT of Toronto, Canada, read this paper. He said the value of heliotherapy in the treatment of certain forms of so-called surgical tuberculosis had been definitely established and especially satisfactory results had been reported in tuberculous disease of the bones and joints, both in closed cases and those with discharging fistulæ. In the latter there was frequently involvement of the skin as well, at the opening of the fistulous tract. Contributions to this subject had been presented to this Association by Brannan and Hinsdale. Dr. Elliott said he had experience with three types of abdominal tuberculosis which had yielded to heliotherapy. (1) Tuberculous enteritis. (2) Tuberculosis of the ileocecal and appendix region. (3) Tuberculous peritonitis with ascites. Illustrative cases of each group were reported. In summarizing he said that in abdominal tuberculosis, heliotherapy would seem to be a valuable addition to simple rest cure in the open air. Good results could be secured at home and in the hospital. The method was applicable even in large cities which had no special climatic advantages, as demonstrated in a city with 46 per cent. possible sunshine.

Appendicitis as a Complication of Pulmonary Tuberculosis. — Dr. HUGH M. KINGHORN of Saranac Lake, N. Y., presented this communication. He stated that from October, 1905, to December, 1914, out of 674 well-established cases of pulmonary tuberculosis, there were 36 cases of appendicitis, or 5.33 per cent. There was an incidence of appendicitis in the male of 6.1 per cent. and against 4.27 in the female. Of these 36 cases 22 were operated upon and 22 recovered without operation. One death occurred from fulminating appendicitis three days after operation. From his experience the writer believed that acute appendicitis in patients suffering with pulmonary tuberculosis should be treated as it would be treated in a normal healthy person. Even feeble patients stood the operation well under nitrous oxide and oxygen. When the appendicitis was not acute and the patient was feeble the pulmonary disease should be considered. These patients stood operation in the interim well.

THE AMERICAN ASSOCIATION OF IMMUNOLOGISTS.

Third Annual Meeting, Held in Washington, D. C., May 11 and 12, 1916.

THE PRESIDENT, DR. JAMES W. JOBLING OF NASHVILLE, IN THE CHAIR.

President's Address: The Relation of Lipoids to Immune Reactions.—DR. JAMES W. JOBLING of Nashville, Tenn., delivered this address, which consisted of a summary to the literature bearing on his subject. He said that according to Meyer and Overton the cell wall was composed chiefly of lipoids, and if this view was ac-

cepted we must concede the possible importance of lipoids in protecting bacteria and the cells of the body against antagonistic substances. Petersen and the writer had shown that bacteria were protected from the action of ferments by the unsaturated fatty-acid compounds present in the cell and that oxiding agents such as iodine, hydrogen peroxide, etc., would destroy this protective action. Treatment of bacteria with thermostabile immune bodies also rendered them more susceptible to the action of ferments, and experiments which were now being conducted by the writer suggested that these substances acted in a manner somewhat similar to that of oxidizing agents. It must be borne in mind that bacteriolysis was almost never obtained with undiluted immune serum, while bacteriolysis *in vivo*, except in the peritoneal cavity had not been demonstrated. Heiler and Rimpau found that lipoid soluble substances were bactericidal. and that a definite relation existed between this action and the lipoid solubility, narcotizing action and the bactericidal action of the substances tested. Frolin found that lipoid-free corpuscles injected into animals produced agglutinins, but no hemolysis, whereas the lipoids produced lysins. Bang and Forsman obtained complement fixation with immune sera, using the lipoids of the homologous cells as antigens. Thiele and Embleton believed that the different results obtained by different investigators with lipoid extracts from fresh tissues were probably due to the fact that proteins were also present. The differences in the results obtained by the various investigators suggested that lipoids in certain combinations might act as antigens, while the pure lipoids had not this property. Stuber, Dewey, Nuzum and others had shown that certain lipoids, chiefly cholesterol, inhibited phagocytosis. Other experiments suggested that the inhibition of Phagocytosis was not due to injury to the cells. Muller, on the other hand, concluded that bacterial lipoids were unimportant in the process of phagocytosis. Stuber believed that the agglutinins were produced as a result of the stimulus afforded by the fats liberated after destruction of the bacteria. He also found that immune serum extracted with ether lost most of its agglutinating power, and that normal serum to which ether extract was added acquired an agglutinating value almost equal to that of the immune serum from which the extracts were obtained. The serum of normal animals that received intravenous injections of extracts of the immune serum also contained strong agglutinins. Graham stated that ether anesthesia did not affect the agglutination titre of sera. The writer reviewed the literature with relation to hemolysins and lipoids and stated that he and Dr. Bull had demonstrated what they believed to be immune lipases in hemolytic sera, but were unable to show that they were essential for hemolysis. After reviewing the literature in reference to the relation of the lipoids to anaphylaxis, the essayist said that it had been known for some time that serum antitrypsin was increased following the recovery from anaphylactic shock. With this in mind Petersen and he had investigated, first, the action of lipoids when given with the intoxicating dose of antigen, and secondly, the influence of increasing the antitryptic power of the serum. They found that increasing the tryptic power of the serum and the addition of soaps to the intoxicating dose enabled the animal to resist several times the amount of the specific protein fatal for the controls, while a smaller dose of the antigens was required when lipoid free proteins were used. They had also shown that the removal of the lipoidal antiferments from the serum permitted the formation of toxic substances which they had termed "serotoxins." These toxic substances were formed through the action of the serum proteases on the serum proteins as soon as the protective lipoidal substances were removed. They found that while there was no loss of nitrogen from bacteria treated in this manner, there was absorption of serum-antiferment from the serum, and accompanying this loss of antiferment power, a proportionate increase in toxicity. Other experiments showed that the lipoid substances had been absorbed by the bacteria, which now became more resistant to such ferments as trypsin. It might be that similar toxic substances were formed *in vivo* in some of the bacteriemias, for instance, anthrax. The writer then discussed complement deviation in reference to the Wassermann reaction and stated that evidence would go to show that alterations in the lipoid content of the serum had an important bearing on the reaction. After reviewing the present status of our knowledge with reference to the Abderhalden reaction, he considered the relation of lipoid solvents to general infections, and brought out a number of factors that tended to explain the constantly manifest influence of the lipoids in the various immunological and physiological balances. These considerations indicated that the fats and lipoids might play an important rôle in at least some of the immunity reactions.

The Inadequacy of the Anaphylatoxin Theory of Anaphylaxis.—Dr. RICHARD WEIL of New York read this paper. The characteristic features of the test-tube reaction were, (1) that it took place not only through the interaction of an immunological couple, namely, antigen and antibody, but of entirely unrelated sera; (2) that the two factors must be in certain definitely limited quantitive relationships; (3) that it was slow and gradual; (4) that it required the presence of complement. He said that in every one of these features it differed from the anaphylactic reaction in the living animal or in the suspended uterus. The crucial test consisted in the fact that it was impossible to produce the anaphylactic reaction in the animal by conditions which duplicated those in the test-tube, namely, the simultaneous intravenous injection of the two factors, antiserum and antigen. According to the physical theory, the reaction was simply an expression of the alteration of cellular equilibrium which resulted when external antigen was brought into contact with cellular antibody. The characteristics of the reaction were all entirely in keeping with this interpretation. The precipitation reaction in the test-tube, which was not accompanied by the chemical destruction of either factor, (1) was immediate; (2) proceeded in the absence of complement; (3) required relatively large amounts of antibody and relatively minute amounts of antigen. In these respects it was perfectly analogous to the anaphylactic reaction. If in place of the visible alteration, expressed as precipitation in the test-tube, interaction of the two factors *in vivo* was supposed to produce an alteration of cellular equilibrium, such as would act as a cellular stimulus, all the requirements of the problem would be satisfied. In view of the fact that precipitin had been demonstrated to be identical with the sensitizing antibody, this explanation of anaphylaxis seemed almost self-evident. This conception obtained the necessity of postulating an intermediate chemical product, namely, anaphylatoxin; such a postulate was not only superfluous, but it was also entirely incompatible with all of the characteristic features of the reaction.

Additional Facts Concerning the Protein Poison.—Dr. VICTOR C. VAUGHN, of Ann Arbor, presented this communication in which he stated that since his last publication his students and he himself had ascertained the following facts: (1) Casein yields a large percentage of the protein poison. (2) The protein poison after the removal of all traces of mineral acid is strongly acid in and of itself. (3) The protein poison did not give the ninhydrin test, but did so after being split up with the acid. (4) The poison gave a skin reaction in all persons. (5) The poison is not without harm when administered by mouth. (6) Animals might be acutely or chronically poisoned by oral administration. (7) In chronic poisoning by feeding, extensive fatty degeneration results. (8) The protein poisons from diverse proteins were not identical. (9) The protein poison from casein combined with certain unbroken proteins. In this combination the acidity of the poison is neutralized and its physiological action diminished. (10) From the tissues of animals killed with protein poisoning, it may be extracted with acidified alcohol, its presence demonstrated, and the amount roughly estimated by the intravenous injection of guinea pigs.

Studies Regarding the Action of Different Blood Sera Upon Various Tissue Substrates.—Dr. OSCAR BERGHAUSEN made this presentation which was a translation of a paper on this subject by Prof. Emil Abderhalden. He stated that every organism, whether of the plant or animal kingdom, split up with the aid of ferments, composite and possibly also simple combinations into products of simpler molecular size. They enabled the cycle of ubstances from plant to animal and from the latter to the former to be accomplished. It seemed quite clear that when composite substances appeared in the blood where they did not belong ferments appeared which changed their character and simultaneously produced products which were taken up by the cells for further utilization. The whole investigation regarding the existence of fer-

ments arose from the idea that every kind of cell consisted of specifically confined units, which were acted upon during anabolism and catabolism by ferments. During normal conditions the cells did not give off their integral parts, but in metabolic disturbances integral cellular substances might appear in the blood. Many new problems were opened by the finding that after parenteral ingestion of proteins and peptones in the blood plasma, ferments appeared in the blood which could split up these substrates. They did not know whether they were dealing with ferments which had just appeared or whether there were always present proteolytic and peptolytic ferments in the blood plasma. It seemed plausible that existing ferments were not inhibited in any way in their action. Everything, however, pointed to the fact that ferments appeared only after and as soon as the blood-foreign material appeared in the blood. Whence they came was not yet determined. Experimentation had been undertaken to bring the ferments in relation with the immune bodies. After discussing the possible relation of the substrate to the antiferment as held by some he pointed out the weakness of their arguments and said that much research was still necessary. They had busied themselves with a series of experiments to determine under what conditions the proteo- and peptolytic ferments reached the optimum of their action. It seemed tangible that during normal conditions cell-specific ferments migrated from the cells to the blood. They were possibly in some way immediately inactivated. The presence of active ferments would in this case point to a disturbance of inactivation. There were many reasons why this view was not probable. The opinion seemed to be unanimous that there was a specificity in ferment action in relation to substrates, but they could not maintain *a priori* that in the list of proteases and peptases specific adaptation toward definite substrates existed. This problem required further examination. The possibility that during definite disturbances in organs ferments were found in the blood which were adapted to definite substrates had caused much activity among investigators. In the course of time from clinics, hospitals and physicians they had received 1,000 specimens of serums with the request to determine the splitting up of this or that organ. Most frequently the question was one regarding the existence of a tumor. All of the examinations might be classified into three groups. In one the clinical diagnosis was known and for these Abderhalden made the examination himself. In the second group he knew the clinical diagnosis; the reaction, however, was carried on by some one who was purposely allowed to remain ignorant of the diagnosis. In the last group the clinical diagnosis was unknown to them. In all cases several organs and tissues were used. There were numerous examples of undoubted specific actions. The quantity of serum in many instances was insufficient for the examination of as many substrates as they wished, so that many of the examinations were not entirely satisfactory. It seemed from this study not impossible that the several varieties of tumors owed their origin to the cessation of function of definite organs. They had commenced in the case of tumor carriers, to look for splitting up of definite organs, such as thyroid, pituitary, thymus, sexual glands, etc. The existing material was still too small to prophesy that research in this direction would be successful. Included in this report were also the results of experiments concerning the production of ferments by parenteral injection of tumor cells which reacted with degnite tumor substrate. It was of much interest that in some isolated cases ferments did not appear. If the serum was found infected, then with regularity no specific action was discernible. If the serum was sterile, then it split up, even after it was kept eight months, that substrate with which it originally reacted. One thing they had learned in their investigations and that was that it paid to investigate the field of pathology with the methods they had used.

The Specific Character of Immunity Reactions.—Dr. E. C. L. Miller of Richmond, Va., said that for many years it had been recognized that immunity reactions were specific. However, when more detailed study was given to some of these reactions, their specific character was less sharply defined. For instance, if a rabbit were repeatedly injected with the blood of a sheep, its serum would react not only to sheep blood but also, to a less extent, to the blood of goats; if injected with horse serum, it would react not only to horse blood but also, to a lesser extent, to the blood of asses and zebras; if injected with human blood the serum would react to the blood of the higher apes. These had been called group reactions and were taken to indicate that the members of the group had somewhere in the past a common ancestor. The blood was not the only tissue that might be used. The cells of any organ if injected into a rabbit would produce a serum that would dissolve such cells. If completely organic specific sera could be prepared they might be of great practical value. Investigators had found that various organs of guinea-pigs, dogs, cats, fowls, turtles, and mice, when injected into rabbits, produced sera hemolytic for sheep corpuscles. In some cases the blood serum of these animals was effective, but in no case would the red corpuscles so act. Strangely enough the organs of sheep and goats produced such hemolysis but very incompletely. Extensive search had been made to find substances that as antigens would produce a common antibody, namely, sheep hemolysin. The essayist reviewed the work of investigators in this search, and said a suggestion looking towards an explanation might be found in some work of Osborne and Wells. They worked with Osborne's pure vegetable proteins and used anaphylaxis for their biological reaction. A review of this work indicated that the specific character of the protein, at least for the anaphylactic reaction and probably also for other biological reactions, depended not on the protein as a whole but on certain parts or qualities or chemical groups in the protein molecule. The reason why biologically related proteins reacted similarly was because they had inherited certain common groups from a common ancestor, but it should cause no surprise that entirely unrelated species occasionally possessed common groups.

Dr. H. Gideon Wells of Chicago said that in all the problems of immunology, specificity was the vital point which could never be overlooked without disaster. In studying the principles of immunology there had been great difficulties because of failure to grasp the essential principles as laid down by Jacques Loeb, namely, that in studying the fundamental principles of biological processes one must reduce the elements involved to the simplest possible, for at the best the reactions were complex and beyond our interpretation. Unfortunately we could not get below the whole protein molecule as one end of our reactions and generally must use the warm blooded mammals for the other side of the equation, although possible work on cell cultures might help us to simplify our materials. The best one could do therefore was to use pure protein, and fortunately there were some proteins that could be obtained in a relatively pure condition, such as non-coagulable ovomucoid of egg-white or alcohol soluble proteins of the grains. Using such isolated proteins, and others, the writer said they had found evidence that, delicate as the specificity of immunological reactions seemed to be, immunological differences did not seem to occur between proteins that could not also be differentiated chemically. The specificity differences of the different proteins seemed to agree with differences in chemical composition, and as yet they had not found finer differences such as might be expected, such as stereoisomeric differences with identical chemical composition. Dr. Osborne and the writer had found in many cases that proteins which were isolated by chemical means could be checked up very nicely as to their individuality by anaphylaxis and other immunological reactions, and immunological methods had been found to be of much help in establishing the chemical identity of unknown proteins.

Dr. John A. Kolmer of Philadelphia said it would be difficult to improve on the excellent résumé presented by Dr. Jobling on the relation of lipoids to immunity. It had been amply proven that toxic substances might be prepared of various animals and vegetable proteins by the method employed by Dr. Vaughan; that likewise toxic substances could be produced in normal and immune sera by the addition of such substances as kaolin and agar capable of producing anaphylaxis-like symptoms and lesions in experimental animals, but that it was not yet clear what relation these observations bore to the mechanism of anaphylaxis, and particularly so in view of the work presented by Dr. Novy within the past few days. Dr. Kolmer said he would like to ask Dr. Vaughan if he was prepared to make any further statement in regard to the relation between his protein poison and the mechanism of anaphylaxis. He would like to know whether Dr. Miller had made careful titrations of the content of antisheep hemolysin in the sera of his rabbits before immunization, as the sera of

a large proportion of these animals contained natural antisheep hemolysin. Dr. Kolmer said that in his opinion "group reactions" in immunity were best explained at the present time according to the views expressed by Dr. Wells in his discussion.

Dr. JOBLING said that, as Dr. Weil had stated, recent work showed that the intoxicating dose in anaphylaxis probably acted first on the cells. In guinea-pigs it caused a contraction of the muscle cells of the bronchi to such a degree that immediate death ensued from asphyxia. In dogs, however, death did not occur for several hours, and the clinical picture was quite different. In the latter case they had observed definite changes in the blood, and they believed that death was probably due to the products of protein cleavage. The ferments, which were greatly increased in amount, were probably liberated as a result of the cell stimulation, and their activity was dependent upon colloidal changes which had taken place when the antigen was brought into contact with the serum. They had observed a definite increase in the higher and lower protein cleavage products in the blood. These they believed were derived from the serum proteins and not from those introduced.

Dr. V. VAUGHAN said he had watched Dr. Novy's experiment with the deepest interest and had observed the appearing and disappearing and reappearing wave of toxicity in serums being incubated with agar and other foreign bodies. He had spent much time trying to measure these waves and to catch the rhythm of the toxicity, but without results. He was not yet ready to abandon the idea that a protein poison was formed in anaphylactic shock. No one could tell whether this was due to a chemical or a physical process, for it was difficult to draw a line between the two. He said that he could conceive that a body so complex as the protein molecule might be dissociated and a poisonous action developed even by high dilution. If so stable a body as sodium chloride could be broken down into its ions by dilution, was it not possible that even more marked alterations might occur in a highly complex molecule. He felt convinced of the fact that the blood contained proteins from which a poisonous group was easily detached.

Dr. WEIL, in closing the discussion, said he was not particularly interested in establishing the universal validity of any of the current theories of anaphylaxis. Attempts of this sort had done more in the past to obscure the truth than to advance it. Time, however, had completely established the truth of the cellular theory, so that in the guinea pig, at all events, it seemed certain that serum changes, with the production of so-called anaphylotoxin, could play no rôle in the typical evolution of shock. It would, however, be just as serious a mistake to assume that the process which took place in the guinea pig must necessarily be universally applicable to the anaphylactic phenomenon throughout the animal kingdom, for it was known with certainty that serum changes of chemical nature accompanied anaphylactic shock in the dog. This fact, however, by no means argued that these changes were productive of the anaphylactic symptoms. It still remained to determine whether serum changes in the dog resulting in the production of some unidentified substance described as anaphylotoxin were simply an accompaniment of anaphylactic shock in that animal, or were actually productive of the symptoms thereof.

The Phenomenon of Leucocytosis and Its Importance as a Diagnostic Sign in Vaccine Treatment.—Dr. JOSEPH HEAD of Philadelphia said that leucocytosis had always been regarded as a symptom of serious inflammatory infection. And yet it had appeared among his patients so frequently as a passing phase of a few days' duration, coming and going without any apparent significance, that he had come to regard a temporary leucocytosis of from 30,000 to 40,000 with considerable complacency. He had taken 54 of his vaccine patients as they came, and had gone over their blood charts with the purpose of getting data on this important subject. Of these 54 cases 33 did not in the course of the treatment give a leucocyte count of over 20,000, but 21 did show transitory leucocyte counts that jumped in some instances from five, six or seven thousand to forty, sixty or one hundred thousand, only in a few days to sink back to four or eight thousand, with no symptoms to speak of or only a slight indisposition. If these observations meant anything at all they certainly meant that a transient high leucocyte count could not be considered of itself an infallible sign of pus or even a semiacute inflammation of a serious nature. Persistence of the leucocytosis accompanied by a falling off of the red cells and hemoglobin would indicate a condition of an entirely different significance.

The Action and Therapeutic Effects of Leucocytic Extract (Archibald).—Dr. W. E. RICHARD SCHOTSTEADT of Fresno, Cal., presented this paper, which was read by W. J. Stone of Toledo, Ohio. He described the work that he had carried on with the leucocytic extract prepared from the blood of normal animals. Subcutaneous injections in normal human beings and in patients suffering from acute infections produced a marked leucocytosis. The leucocyte increase was often 300 per cent., and was highest within ten to twelve hours after the administration. The increase in the neutrophile elements was particularly marked and coincident with it was a less marked increase in the eosinophile cells. Clinically strikingly beneficial results in man had been obtained following its use in acute infections such as furunculosis, pneumonia, bronchitis, and acute tonsillitis. Chronic infections had shown a less striking improvement, though the leucocytic increase had been as marked as in the above cases.

Dr. GEORGE H. ROBINSON of Glenolden, Pa., said that from a clinical standpoint the work of Dr. Head had very important bearings. In mouth infections there were two features that were very important, not only was there a very high eosinophile count, but other conditions as well that were difficult to explain. He had used a bacterial extract unactivated made from the discharges of old sinuses, and he thought this produced what might be called fixation abscesses.

Dr. WILLIAM LINTZ of Brooklyn said he had made experiments in guinea pigs and rats, inoculating them every two hours, and it had been interesting to note the marked polymorphonuclear count that followed as well as the marked leucocytosis. Out of fifteen or eighteen cases of pneumonia in which there was a decided leucocytosis, with but one exception, none were benefitted by the use of the leucocytic extract.

Allergic Skin Reactions as an Index of Immunity.—Dr. JOHN A. KOLMER of Philadelphia said that these experiments were undertaken primarily to determine if the sera of persons and animals reacting positively and negatively to various allergic skin tests contained lytic antibodies for the corresponding living microorganisms and, if so, whether or not these antibodies bore a quantitative relationship to the allergic reactions; secondarily to determine the relationship, if any, among bacteriolytic, agglutinating, and complement-fixing antibodies in the sera of persons and animals reacting variously to allergic skin tests. He remarked that the sera of normal persons possessed a marked bactericidal power for *B. typhosus;* the bacteriolysin content for *B. typhosus* in the sera of normal persons and persons who had typhoid fever or had been immunized with typhoid vaccine was high but bore no relation to the typhoid in skin reactions. The sera of syphilitic persons in the tertiary stages who reacted positively and negatively to the luetin skin test and the sera of normal persons showed no appreciable spirochetal activity for a pure culture of *T. pallidum.* The sera of persons reacting positively and negatively to the intracutaneous injection of a washed polyvalent antigen of diptheria bacilli showed an abscence of bactericidal power for *B. diptheriæ.* The sera of dogs suffering with distemper and also the sera of healthy dogs and dogs immunized with *B. bronchisepticus* and reacting positively and negatively to an intracutaneous allergic reaction were found to be without appreciable bactericidal power for *B. bronchisepticus.* Agglutinins and complement-fixing antibodies in the sera of persons and animals for these various microorganisms bore no relation to the skin reactions. These studies demonstrated that there was no experimental support for the theory that allergic skin reactions might be taken as an index to resistance and immunity in so far as it was possible to determine the presence of antibodies *in vitro.*

(To be continued.)

Long Lives of the Presidents.—A writer in the *Lancet* calls attention to the many instances of longevity among the presidents of the United States, the average age of whom was 69 years, and were it not for the cutting short of the lives of Lincoln, Garfield, and McKinley by assassination at 56, 49, and 58 respectively this average would be even higher. Four of the twenty-four lived to the ages of 80, 83, 85, and 90 years.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF MARYLAND.
June 20, 1916.

(*Concluded from page* 574.)

PATHOLOGY.

1. What are infective granulomata? Mention several and describe one.
2. Briefly discuss teratomata.
3. Describe ingrowing toenail.
4. What are anaerobic bacteria? Classify, and mention an organism belonging to each class.
5. Describe keloid tissue.
6. Define the terms secretion, excretion, transudate, exudate.
7. What is meant by "sensitization"?
8. What are the general characteristics of sarcoma in contrast to carcinoma?
9. Describe the beef tape worm.
10. What are the means used to prove that death has positively occurred? What is rigor mortis?

PRACTICE OF MEDICINE.

1. What diseases are liable to occur in the right inguinal region?
2. Give signs and symptoms of floating kidney.
3. Give causes of malaria and varieties of organisms.
4. Name the eruptive fevers and also give period of incubation in each.
5. What is hemophilia and how treated?
6. Differentiate the terms delusion and hallucination and also define the terms epistaxis, hemoptysis, and hematemesis.
7. Give symptoms of diabetus mellitus and treatment.
8. Name causes of interstitial nephritis and the more common complications.
9. Describe empyema; give diagnosis and treatment.
10. Give differential diagnosis between gout and arthritis deformans.

OBSTETRICS AND GYNECOLOGY.

1. Define a trefoil, horseshoe, succenturiate, and battledore placenta.
2. What is a caput succedaneum and how is it formed?
3. Describe your method of preventing lacerations of the perineum during delivery.
4. What is your treatment in the delivery of twins with heads interlocked?
5. What is the danger of a prolapsed cord and how do you treat it?
6. What is phlegmasia alba dolens, its cause and treatment?
7. How do you diagnose a face from a breech presentation?
8. Why is a face presentation hard to deliver?
9. Give differential diagnosis between a retroflexed gravid uterus, and a pregnancy complicated by ovarian tumor.
10. What is the usual cause of salpingitis? Describe its course and treatment.

SURGERY.

1. Give cause and treatment of chronic suppuration of the middle ear.
2. Give diagnosis, symptoms, and treatment of gonorrheal conjunctivitis.
3. Give signs, symptoms, diagnosis, complications, and treatment of phlebitis.
4. Give symptoms and treatment of Pott's disease.
5. Give the differential diagnosis between fracture of neck of humerus and dislocation of shoulder joint. Outline the treatment of one.
6. What are the causes of ischiorectal abscesses? Give symptoms and treatment.
7. Describe a rodent ulcer. Give the structures in which rodent ulcer mostly develops, and give surgical treatment.
8. If called to a patient with a compound fracture of a leg in the lower third, which had been kicked by a horse in a barnyard, state in detail how you would treat such a case.
9. Give varieties of ileus, and some of the causes of each. Outline treatment.
10. Give the symptoms and physical signs of carcinoma of the breast.

ANSWERS.

PATHOLOGY.

1. *Infective granulomata* are inflammatory new growths due to protozoa, bacteria or parasites. They are found in tuberculosis, lupus, syphilis, leprosy, glanders, and actinomycosis.

The *tubercle* is a mass of new formed connective tissue cells, consisting of three layers: (1) lymphoid cells externally, (2) epitheliod cells, in the middle, and (3) giant cells in the center; the tubercle bacilli may be found in (2) and (3).

2. *Teratomata* are "tumors which have a tendency to the formation not only of irregular cell masses but also of fully formed organs, such as brain, teeth, skin, hair, bone, or secreting glands. Such growths may be due to the development of two germinal areas on one germinal vesicle, giving rise to double monsters, one of which undergoes inclusion in the other—fetal inclusion. They may result from the displacement of totipotential cells—those capable of giving origin to an individual—which become included in the growing organism. These cells may develop early, and grow elaborately, giving rise to inclusions recognizable at birth. They may lie latent and at a subsequent time grow actively as abdominal inclusions, teratomata of the genital glands, and certain mixed tumors. *Dermoid cysts, ovarian dermoids* are the most common of the teratomata. The cyst cavity is lined by squamous epithelium, in which are found sweat and sebaceous glands. Within the cavity is usually a varying amount of fatty material in which are masses of hair. In the wall of the cyst are found masses of bone to which teeth, usually but poorly formed, are attached. In some instances the extremities and genitalia have been seen. Somewhat similar growths may be found in those parts of the body where fetal clefts have united and in the median fissures of the body. There is another type, the *sporadic teratomata*, which grow in regions bearing no relationship to the fissures, to the poles of the body, or to the generative glands, as in the anterior mediastinum and the abdomen. These are probably due to the development of a misplaced totipotential cell. They generally consist of tissue from all three germinal layers. Sometimes the tissues are of adult appearance and of limited growth. More frequently they appear about puberty, grow rapidly, and tend to form secondary tumors."—(McConnell's *Manual of Pathology.*)

3. *Ingrowing toenail.* "This is more accurately described as an overgrowth of the soft tissues along the edge of the nail. It is most frequently met with in the great toe in young adults whose feet perspire freely, who wear ill-fitting shoes, and who cut their toenails carelessly or tear them with their fingers. Where the soft tissues are pressed against the edge of the nail, the skin gives way, and there is the formation of exuberant granulations and of discharge which is sometimes fetid. The affection is a painful one, and may unfit the patient for work."—(Thomson and Miles' *Manual of Surgery.*)

4. *Anaerobic bacteria* are such as either cannot exist in the presence of oxygen or such as find the presence of oxygen injurious to their growth. There are two classes: 1. Obligatory anaerobes, which do not grow except in the almost complete absence of free oxygen; example, the bacillus of tetanus. 2. Facultative anaerobes are those which can thrive in either the presence or the absence of oxygen; example, the bacillus of typhoid.

5. *Keloid tissue* is a tissue of fibrous formation which occurs in scar tissue. It is characterized by somewhat luxuriant growth, and is not confined to the site of the original injury and scar formation. It is generally smooth, and is most often found in negroes.

6. *Secretion* is the process by which certain organs (glands and membranes) separate from the blood certain constituents which are further elaborated and serve some further office in the economy.

Excretion is a similar process by which there are removed from the blood waste materials, and products of no further use to the body, and which if retained would be injurious.

Transudate is a fluid which is found in the interstices of the tissues and which has passed through the walls of the blood vessels. It contains very few cellular elements. A transudate which is the result of inflammation is called an *exudate.*

7. *Sensitization* is the rendering of a cell liable to destruction by a complement, through the action of a specific amboceptor.

8.

SARCOMA.	CARCINOMA.
Origin; entirely mesoblastic (Connective-tissue type).	Epiblastic and hypoblastic (Epithelial-tissue type).
Stroma; intercellular. Rarely forms alveoli.	Vascular connective tissue, which surrounds and forms the walls of the alveoli; these communicate with one another, and contain masses of epithelial cells.
Cells; granulation tissue or embryonic connective-tissue cells; shape and size vary.	Epithelial cells contained within alveoli; shape and size vary.
Intercellular substance; may be present.	Absent, or merely fluid.
Vessels; embryonic in character. They are in direct contact with, or may be formed by, the special cells, slightly modified, of which the tumor is composed.	Well developed; entirely contained within the connective tissue stroma, and supported by the walls of the aveoli. Seldom in contact with the cells.

—(Coplin's *Pathology.*)

9. The *beef tape-worm* or *Tænia saginata* or *Tænia mediocanellata* is from 10 to 30 feet in length, and has several hundred proglottides. It has a rounded or oval-shaped head which measures about 1/10 of an inch, and has four strong and prominent suckers, but no hooklets—whence the term "unarmed tapeworm"; the neck is short and thick and the segments are larger, stronger, and thicker than those of the *Tænia solium.* The best way to distinguish a segment of *Tænia saginata* from that of *Tænia solium* is to count the number of lateral uterine branches.

In the *Tænia saginata*, there are 15 to 30 of them; in the *Tænia solium* there are 5 to 10.—(Hughes' *Practice of Medicine.*)

10. *Phenomena and signs of death*, are: The complete and permanent cessation of circulation and respiration, rigor mortis, loss of body heat, pallor of the body, putrefaction.

For methods of applying the tests, see a good textbook on medical jurisprudence.

Rigor mortis is the condlition of rigidity or contraction into which the muscles of the body pass after death. It begins at a period varying from about 15 minutes to about 6 hours. It usually begins in the muscles of the eye, neck, and jaw; then the muscles of the chest and upper extremity, and last of all those of the abdomen and lower extremity are affected. It passes off in the same order in about 24 hours. It is said to be due to the coagulation of the muscle plasma.

PRACTICE OF MEDICINE.

1. *Diseases liable to occur in the right inguinal region:* Appendicitis, inguinal hernia, psoas abscess, intussusception fibroid tumor, fecal impaction, cancer of cecum or ascending colon, floating kidney, cyst or abscess or broad ligament or ovary, retroperitoneal sarcoma.

2. *Signs and symptoms of floating kidney:* There may be a dragging pain in the loin, which is made worse by exertion; there may be paroxysmal crises of pain accompanied by rigor, vomiting and collapse (Dietl's crises); neurasthenia, and dyspepsia may be present; the kidney may be palpated in the abdominal cavity and may be replaced. There may be no symptoms at all.

3. The *cause of malaria* is the *plasmodium malariæ*, which is inoculated in man by the anopheles mosquito. There are three varieties of parasite: 1. The quartan parasite (*Plasmodium malariæ*); 2. the tertian parasite (*Plasmodium vivax*); and the æstivo-autumnal parasite (*Plasmodium falciparum*).

4. *Eruptive fevers, with period of incubation* (approximate): Typhoid, five to twenty-one- days; typhus, three or four to fourteen days; measles, one to two weeks; German measles, five to twenty days; scarlatina, three to seven days; smallpox, ten to fourteen days; chickenpox, fourteen or fifteen days; erysipelas, three to seven days.

5. *Hemophilia* is a condition characterized by a tendency to severe hemorrhage, sometimes almost uncontrollable, and following any slight injury or abrasion. Heredity is a common factor, and males are most commonly affected, but the disease is transmitted through females. *Treatment* consists in protection from injury or operation; adrenalin, calcium lactate, ergot, ferric chloride, potassium chlorate, ice, tannic acid, fibrin ferment, and other remedies have been suggested; transfusion of blood may be necessary.

6. A *delusion* is a belief in something which has no real existence, but is purely imaginary, and out of which the person cannot be reasoned. An *illusion* is a false or perverted impression, received through one of the senses. An *hallucination* is the same as an illusion, but without any material basis.

If an individual believes himself to be made of glass, and is afraid of being touched lest he be broken, he is suffering from a *delusion.* If the whistling of the wind is mistaken for a voice telling a person to do a certain thing, that would be an *illusion.* If a person fancied he heard a voice when there was nothing at all to be heard, that would be an *hallucination.*

Epistaxis is bleeding from the nose.

Hemoptysis is the spitting of blood.

Hematemesis is the vomiting of blood.

7. The *symptoms of diabetes mellitus* are: Weakness, excessive thirst, frequent urination, and increase in the amount of urine voided, the presence of glucose in the urine. Hyperglycemia is a feature of the disease; pruritus, emaciation, a dry and harsh skin, lost or diminished knee-jerks, coma, and air hunger are often present. The urine also contains acetone, oxybutyric acid, and diacetic acid, sometimes albumin and casts, and an increased output of nitrogen.

The *treatment* is mainly *dietetic.* "The indications are to maintain nutrition, to increase the tolerance for carbohydrates, to lessen hyperglycemia, and to prevent or diminish acidosis. In mild cases (except in childhood and adolescence) the diet may contain the full amount of carbohydrate that can be tolerated without causing glycosuria, but a week of strict (carbohydrate-free) diet should be interposed every four or five weeks. In severe cases with acidosis, the diet should have a low nitrogen content and contain the carbohydrate best tolerated (oatmeal, potato, fruit) in such quantity that the glycosuria is kept at a minimum and the body weight is not reduced. Frequent periods of strict diet must be introduced, however, to lessen the hyperglycemia, and during these periods from ½ to 1 ounce of sodium bicarbonate should be given daily to control the acidosis. In cases requiring rigorous treatment alcohol in moderate amounts, in the form of whiskey, brandy, or white wine, is useful in supplying additional energy and aiding in the digestion of fats. *General hygienic measures* are of great importance, especially the prevention of mental and physical overexertion, worry, and excitement. A moderate amount of regulated exercise is beneficial in mild cases, but considerable rest is absolutely necessary in severe forms of the disease. *Drugs.*—Tonics, like arsenic, iron and strychnine are often useful. Opium proves efficacious in some cases. It is best given in the form of codeine (½ grain three or four times a day). Salicylates have been strongly recommended. Bromides are serviceable in subduing nervous manifestations. Alkaline carbonates and alkaline mineral waters have long enjoyed a reputation. Upon the recognition of the early signs of *coma*, a moderate amount of readily digestible carbohydrate should be added to the diet. Absolute rest should be enforced, saline laxatives and diuretics (theobromine caffeine), should be administered, and large doses (1 to 2 ounces) of sodium bicarbonate should be given daily. Developed coma is rarely relieved by *intravenous* injections of 4 per cent. solution of sodium carbonate (a liter, if possible, and repeated if necessary at end of six hours)."—(Stevens' *Practice of Medicine.*)

8. *The causes of chronic interstitial nephritis* are practically the same as for arteriosclerosis. The disease may be traced to chronic alcoholism, gout, chronic lead poisoning, syphilis, and diabetes. Age is, of course, a factor; so too, are overwork, high living, and worry. *Complications:*—Bronchitis, pleurisy, pneumonia, pericarditis, endocarditis, and other inflammatory conditions, edema, and various hemorrhages.

9. *Empyema* is generally secondary to pneumonia, tuberculosis, scarlet fever, or other exanthem, suppurative inflammations, or traumatism. The pneumococcus, streptococcus, and staphylococcus are the bacteria most frequently found. The condition is diagnosed by finding the symptoms of fluid in the pleural cavity; this is withdrawn by a needle and on examination is found to be pus; a leucocytosis is also present.

The physical signs are those of fluid in the pleural cavity; that side does not move well, the percussion note

is dull, there is absence of breath sounds, vocal fremitus and resonance are diminished. Let alone, an empyema may burst through an intercostal space, usually the fifth. The lung is collapsed in extent according to the amount of pus. The pleura, at first covered with lymph, soon becomes covered with layers of granulation tissue, the deeper part of which is converted into fibrocicatricial tissue, and the lung itself also undergoes some fibroid change. If the pus is let out early the lung and pleura soon expand, but if allowed to go on the infiltration of the lung and the density of the scar tissue covering it hinder expansion. Nature attempts to remedy this in various ways. (1) The other lung expands and pushes the heart over to the opposite side; (2) the chest wall falls in, the intercostal spaces are obliterated, and the spine is curved, with its concavity toward that side; (3) the abdominal viscera are pushed up; and (4) exuberant granulations form on the pleura. If a cavity still remains an operation is necessary.

Symptoms: Fever, sweats, chill, diminished breath sounds and vocal fremitus, impaired mobility of chest, dullness on affected side, heart displaced to opposite side, leucocytosis.

Treatment: Aspiration, drainage, irrigation, resection of ribs (Estlander's operation), or resection of chest wall (Schede's operation). Operation of some sort is the only treatment.

10.

GOUT.	RHEUMATOID ARTHRITIS.
Frequently hereditary.	Not so.
Causes are chiefly dietetic.	Causes chiefly nervous.
Affects males and the better classes most frequently.	Affects females and lower classes most frequently.
Begins in the big toe and extends to other toes; it is unilateral.	Begins in the fingers which point to the ulnar side; develops in symmetric order.
Attacks are periodic.	More steadily progressive.
Deformity due to tophaceous deposits.	Deformity due to exostosis and ankylosis, and more marked.
Uric acid in excess in the blood.	Not so.
Complications (nephritis, arteriosclerosis).	Very rare.

—(Anders' *Practice of Medicine.*)

OBSTETRICS AND GYNECOLOGY.

1. A *trefoil placenta* is a malformation of the placenta in which there are three distinct portions of that organ, more or less intimately united.

A *horseshoe placenta* is a placenta which has a crescentic form, seen in cases of placenta prævia when the placenta is found around the internal os; it is also found in some cases of twin pregnancy where the two placentæ are joined by a strip of placental tissue.

A *succenturiate placenta* is one which, in addition to the usual placenta, has one or more subsidiary lobes.

Battledore placenta is one in which the cord is implanted in the margin instead of in the center.

2. *Caput succedaneum* is an edematous swelling developed on the presenting part in the course of birth. It is formed by the serosanguineous infiltration of the connective tissue of the presenting part and is due to edema in the part which is not compressed by the maternal structures.

3. *To protect the perineum:* The patient should be restrained from bearing down unduly; extension of the head must be retarded, and the central part of the occiput must be allowed to be born first; pressure must be made with the hand between the coccyx and the anus; when the perineum has had time to stretch, extension and expulsion are allowed; after the birth of the head care must be taken to see that the perineum is not torn by the birth of the shoulders.

4. *Management of twin labor complicated by interlocking.* "If there is marked delay in the delivery of the first twin, some form of interlocking should be suspected and under anesthesia the hand should be passed into the uterus and the exact conditions determined. If both twins present by the vertex and the second has become impacted in the neck of the first child, an attempt should be made to push up the second head and deliver the first child with the forceps. Occasionally, the best procedure is to deliver the second head past the first, always remembering that craniotomy on one child in the hope of saving the other may be good obstetrics. If the first child presents by the breech and its body is born while its chin is locked with the chin of its fellow, an attempt should be made to unlock the heads, but if this attempt fails it is usually wise to decapitate the first child, pushing up its head, and then to deliver the second child, finally delivering the head of the first. The reason for the wisdom of this course lies in the fact that with failure of the attempt to dislodge the second child's head, the life of the first child usually ceases during the endeavor to extract the second past it, and the second child's life is much more likely to be saved if the canal is cleared of the first child. If the first child lies transversely, and the second child sits astride with feet in the vagina the best procedure is usually to perform version and extraction upon the first child, although each of these cases presents a problem of its own and must be dealt with individually, some cases justifying cesarean section and some craniotomy."—(Cragin's *Practice of Obstetrics.*)

5. PROLAPSED CORD. *Danger:* Compression causes death of the fetus. *Treatment of prolapsed funis* consists in : (1) Not rupturing the membranes prematurely unless there is some positive indication; (2) postural treatment, in which the woman is placed on her back or on the opposite side to that on which the cord lies, with hips and pelvis elevated, or the knee-chest position may be adopted; (3) reposition of the cord, either manually or with some form of repositor; (4) speedy delivery, by forceps or podalic version.

6. PHLEGMASIA ALBA DOLENS is a form of manifestation of puerperal sepsis in which there is a thrombosis of the iliac or femoral vein. Sometimes it occurs after a uterine phlebitis, in which clots are carried from the uterine sinuses to the hypogastric veins, where they cause obstruction to the blood flow in the crural veins. The trouble may also begin as a crural phlebitis. It is thus due either to cellulitis or to thrombosis. It usually appears about the third or fourth week of the puerperium. *Symptoms:* Irregular chilliness and malaise, pain in leg and abdomen, rigor and swelling of leg, fever, skin is white and tense, and the vein feels hard. *Treatment:* Rest in bed, support patient's strength, relieve pain, and apply lead and opium wash to take down the inflammation.

7.

BREECH.	FACE.
Abdominal palpation will reveal the movable head above, upon which cephalic ballottement may be practised.	Abdominal palpation will show the breech and extremities above.
The anus may be distinguished by the absence of bony ridges, by its small size, and by the sphincteric action.	The mouth may be recognized by its large size, by the presence of the hard bony alveolar ridges, and by the absence of sphincteric action.
There is a discharge of meconium.	No meconium is discharged.
The sharp spinous processes of the sacrum may be felt.	There are no corresponding processes to be detected.
There are no other prominent bony structures to be distinguished.	There is to be noted the presence of the hard orbital borders and the smooth, broad forehead.

—(Dorland's *Obstetrics.*)

8. A *face presentation* is hard to deliver, because, unless the head is fully extended large diameters engage (*e.g.* vertico-mental diameter, of about 4½ inches); further, the face bones do not mould, the membranes rupture early, and the face is a bad dilator.

9.

RETROFLEXED GRAVID UTERUS.	PREGNANCY WITH OVARIAN TUMOR.
Symptoms of incarceration early.	Absent or very late.
Bladder symptoms pronounced.	Absent or inconsiderable.
Tumor symmetric and soft all over.	Usually asymmetric, hard, and tense all over or in places.
No other tumor above the pelvis.	Often can feel pregnant uterus above inlet and to one side.

RETOFLEXED GRAVID UTERUS	PREGNANCY WITH OVARIAN TUMOR
Moving the cervix imparts impulse to the tumor.	The upper tumor (uterus) can be moved independently of tumor.
The fornices are flattened, at least not drawn up.	The fornices are drawn up high, sometimes even above the pubis.
The tumor in the cul-de-sac may contract.	Never.
May distinguish the fetal parts.	Never.

—(De Lee's *Obstetrics.*)

10. Salpingitis. The usual cause is septic infection, or gonorrhea. *Diagnosis:* A dragging sensation in the neighborhood of the affected tube; colicky pain, which is increased on exertion or even on standing; abdominal tenderness; menstrual disorders, as amenorrhea, metrorrhagia, dysmenorrhea, menorrhagia; dyspareunia; there may be septic symptoms and peritonitis; sterility generally ensues. On examination there will be found a fullness in Douglas' pouch and one or both lateral fornices; in these latter will be felt either the tubes, distorted and possibly adherent, or a sausage-shaped tumor, which is very painful; the uterus is retroverted or retroflexed, and may be bound down by adhesions; there may be an intermittent expulsion of pus accompanied and preceded by a burning pelvic pain.

Treatment: Rest in bed, hot vaginal douches, saline purgatives, liquid diet, morphine (if necessary) for pain, removal of pathological conditions and complications; radical operation (salpingectomy, or salpingo-oophorectomy) may be necessary.

SURGERY.

1. *Chronic suppuration of the middle ear* is due to the permanent lodgment of staphylococci in the acutely inflamed middle ear. This is usually brought about by improper (*i.e.*, excessive) treatment of acute otitis media. *Treatment:* "Cotton must never be worn in the discharging ear. The discharge must be mopped out, but if very thick and copious, syringing by means of sterile water or sterile water containing salt (gr. 5-℥ 1) or carbolic acid (1:40), once or twice in 24 hours in bad cases is permissible. After mopping the ear, 10 drops of an antiseptic solution may be instilled. Formalin solution (1:1000-1:2000), carbolic acid solution (1:40), or, if granulations are present, absolute alcohol, may be dropped in and allowed to remain for a few minutes, and then turned out into a towel. This treatment should be continued once or twice a day in very bad cases, and less often when the discharge decreases. If, after several months, improvement does not take place removal of the ossicles under general anesthesia may be necessary."—(*Pocket Cyclopedia*).

2. Gonorrheal Conjunctivitis. *Symptoms:* Swelling and redness of the eyes, the presence of a discharge which soon becomes purulent, the conjunctiva of the lids becomes thickened, the eyelids are edematous, pain is severe, and there is some fever.

Diagnosis is made by the history, the symptoms, and finding the gonococcus in the purulent discharge.

Management: Protect the sound eye. Wash the eye carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped onto the cornea every night and morning. The eyes must be covered with a light, cold wet compress. The patient must be isolated, and all cloths and compresses used must be burned. In adults the irrigation must be frequent, about every half hour or hour.

3. Phlebitis. *Symptoms:* A hard, painful, cord-like swelling forms over the vein. Skin over this is dusky, congested, and edematous. If the vein is superficial there are no other signs. If it is the main deep vein of the limb, massive solid edema occurs, with considerable lymphatic engorgement (white leg). Superficial veins enlarge in order to carry on the collateral circulation. Fever, with rigors, occurs, and is proportioned to the infectivity of the process. Abscesses develop round an infective phlebitis. *Complications:* Cardiac or pulmonary embolism follow the dislodgement of a thrombus. Pyemia results from the disintegration of a septic thrombus. Permanent edema with varicose veins is left in the leg when the deep femoral is blocked. *Treatment:* Rest and elevation in bed for six weeks. Belladonna applications for pain. Excision of the veins in recurrent superficial phlebitis. Incision, removal of clot with proximal ligature in infective phlebitis, *e.g.*, in the juglar vein following acute mastoiditis.—(*Synopsis of Surgery.*)

4. *Pott's disease* is tuberculosis of the spine. The *symptoms* are pain, tenderness on pressure, rigidity of the back, and a sense of weakness, which may usually be recognized by the child's actions. When suppuration occurs, the pus may enter the sheath of the psoas, destroying the muscle, and presenting in the iliac fossa or groin as an iliac or psoas abscess; or it may pass backward through or external to the quadratus lumborum, and point in the loin, when it is known as lumbar abscess. In the cervical region retropharyngeal abscess may occur. Spinal paralysis may come on at any time and myelitis develops in the latter stages. *Treatment:* "Rest in bed, using sand bags as splints, is the first consideration. After the acute symptoms have subsided a Thomas splint, Sayre's plaster cast, or Cocking's felt jacket may be applied to the back and the patient gradually allowed to move about. *To apply the plaster-of-Paris cast,* the patient should be suspended so that the heels are just off the ground. A skin-fitting vest is then applied to the trunk, under which a stomach-pad is inserted, which should be removed after the plaster has become dry. Plaster bandages should now be applied in the usual manner, extending from the level of the axilla to just below the crest of the ilium. When the case is dry, it may be divided down the front and perforated, so that it can be laced up or removed at any time. Abscesses should be opened early and freely, and injections of iodoform emulsion will be found very beneficial. Laminectomy is sometimes advisable."—(*Pocket Cyclopedia.*)

5. In *fracture of the surgical neck of the humerus,* the head of the humerus will be found in the glenoid cavity, but it will not rotate with the shaft; the arm will appear shorter; and crepitus and abnormal mobility will be elicited unless there is impaction.

In *dislocation of the shoulder joint,* the glenoid cavity will be empty, and the head of the bone will be found in an abnormal position; the arm will appear longer; there will be no crepitus, and no abnormal mobility.

Recent dislocation of the shoulder. Kocher's method of reduction is: to flex the forearm, press the elbow to the side, rotate the arm outward. Bring the arm forward and upward to a right angle with the body, then rotate inward, while the elbow is brought down over the body so that the fingers sweep the opposite shoulder.

6. *Ischiorectal abscess. Causes:* Infection of the ischiorectal tissues with pyogenic microorganisms; skin infection; infection from rectum; trauma. *Symptoms:* Severe and throbbing pain in perineum and round anus, great tenderness, edema, redness of skin, fever, and signs of pus formation. *Treatment:* Free incision, opening up every part of the abscess; do not wait for fluctuation. Irrigate and drain.

7. "*Rodent ulcer* is a carcinoma beginning in sebaceous glands. It generally occurs in patients over forty, and is of very slow growth. It begins as a smooth, rounded knob in the skin about the nose, eyelids, orbital angles, or cheeks, slowly increasing in size. In time ulceration occurs. The ulcer has a smooth, depressed base covered with ill-formed granulations, and bounded by a slightly raised, indurated, rolled-over edge. There is little discharge if sepsis is prevented, and little or no pain. The lmpyhatic vessels and glands are not affected, and dissemination does not occur. The ulcer spreads and destroys surrounding structures; even bone is not spared, so that the brain may ultimately be exposed. Microscopically the growth resembles epithelioma, but the cells are never of the 'prickle-cell' type, and no 'cell nests' are found. The cell columns spread more laterally than deeply, and there is less small-celled infiltration around. *Treatment:* Free incision, allowing a margin of ½ inch all around. If the situation or extent do not allow of this, Röntgen rays should be used for ten minutes daily till healing occurs."—(*Aids to Surgery.*)

8. "In the treatment of compound fractures the main object is to render the wound aseptic and to give efficient exit to the discharges. For this purpose the patient should in all cases be anesthetized, the limb shaved, and thoroughly purified, and the wound enlarged and thoroughly washed out with some reliable antiseptic. It may be advisable to excise torn and dirty fragments of skin, muscle, and tendon, especially when dirt has been ground into them. Loose fragments of bone are removed and portions denuded of their periosteum may be taken away lest necrosis should ensue; where fragments retain any considerable connection with the soft parts

they may be left without fear. When a sharp end of one of the fragments is protruding through a small opening in the skin it is first purified thoroughly before attempting its reduction and then replaced, after enlarging the wound in the skin, or a portion sawn off. Hemorrhage is dealt with in the usual way, and the fragments are placed as nearly as possible in their normal position. If the fragments can be brought accurately into position it is well to fix them by some mechanical appliance; but where the ends of the bone are much comminuted the small portions must be arranged in position as well as possible, and no attempt made to wire them. A good-sized drainage tube is inserted, and, if need be, counter-openings are made; the external wound is closed or not, according to circumstances, and dressed and suitable splints are then applied. Under such a régime the majority of cases do well. Immovable apparatus may be used after a time, windows being left in the plaster casing to allow wounds to be dressed." —(Rose and Carless's *Manual of Surgery.*)

9. ILEUS. *Varieties, with causes:* 1. *Acute*, caused by strangulation by bands and through apertures, kinking, volvulus, foreign bodies, and intussusception. 2. *Chronic*, caused by stricture, fecal accumulation, and tumors (either within or outside the bowel). *Treatment of the acute variety:* "The only thing that can give the patient the chance he ought to have is immediate operation. It is advisable to wash out the stomach before the operation, so that intestinal contents may not be vomited and inhaled during operation.

"Three objects are aimed at: (1) To empty the distended bowel above the obstruction; (2) to relieve the obstruction; (3) to treat the strangulated intestine. In cases that are almost moribund, the abdomen should be opened with cocaine or eucaine anesthesia; a distended coil is pulled out and tapped, a Paul's tube being subsequently tied in. The peritoneal cavity is protected with gauze packing during these manipulations. The bowel is stitched to the abdominal wound after the feces and flatus have drained away. No attempt at relief if the obstruction can be made in these cases till a later date, and, of course, a high death-rate must be expected.

"In less severe cases the abdomen should be opened in the mid-line below the umbilicus, and a systematic search made for the cause of the obstruction. The hernial orifices are first examined, then the cecum. If the cecum is distended, the obstruction lies below it; if collapsed, above it. In the former case the sigmoid should next be examined. If collapsed, the colon must then be traced backwards till the obstruction is found. If the cecum is collapsed, the intestine must be pulled out a foot at a time and examined, beginning with the ileum, and replacing it as each part is done with. If the intestine is much distended, several coils may be tapped and emptied, to facilitate the search.

"Bands and adhesions should be divided between ligatures. A volvulus should be untwisted if possible. If it tends to rewind, the mesosigmoid must be stitched to the abdominal wall. If it cannot be untwisted owing to adhesions, or if the mass is gangrenous, it must be resected if the patient can stand so severe an operation. If not, an artificial anus must be made both in the drawn-out loop and in the colon above it.

"Foreign bodies should be pushed back to a healthy part of the intestine, and removed through an incision at the antimesenteric border, which is afterwards stitched up."—(*Aids to Surgery.*)

10. *Carcinoma of the breast:* "Scirrhous carcinoma is usually met with in women between the ages of thirty-five and fifty, and it often begins while the patient is still menstruating regularly. It sometimes occurs in patients below thirty. The most common site is the upper and outer quadrant of the breast, but it may occur in any part of the gland. Sometimes there is more than one nodule in the breast. In its early stages the condition is quite painless, and the existence of the tumor is usually discovered accidentally. In some cases indrawing of the nipple or dimpling of the skin over the breast first attracts attention. It is often noticed that there is a difference in the level of the two nipples, that of the affected breast being at a higher level than the other (Watson Cheyne). As the disease progresses the patient experiences a dull, aching pain, with occasional sharp twinges shooting through toward the shoulder, up into the neck, or down the inner side of the arm. On palpation, a more or less circumscribed and fairly well-defined tumor of stony hardness may be felt in the substance of the breast. Not being encapsulated, it cannot be moved apart from the breast. When firmly pressed against the chest wall with the flat of the hand the tumor becomes more evident, and its stony hardness is fully appreciated. The skin over the growth may for a long time remain free, but, as the disease progresses, it becomes tacked down, and is later dimpled by contraction of the suspensory ligaments of Cooper. When the skin becomes invaded by the tumor it assumes a characteristically coarse and indurated appearance, aptly compared to that of the skin of an orange or to pig's skin. When the tumor is near the center of the breast, it causes retraction of the nipple by dragging on the large ducts. It cannot be too strongly emphasized that the presence of all or any of these symptoms is not necessary for the diagnosis of cancer, and that when there is any doubt the patient should be given the benefit of an exploratory operation." —(Thomson and Miles' *Manual of Surgery.*)

Therapeutic Hints.

Treatment of Eclampsia.—Knipe and Donnelly show excellent results and a lower mortality rate by the use of the following treatment than by any radical operative measures: Lavage of the stomach; 2 oz. of castor oil given through the stomach tube; 20 to 30 minutes' sweat in the sweat cabinet; hypodermic of morphia, ½ gr. is given if convulsions are violent or frequent; hypodermoclysis after the first sweat followed by proctoclysis midway between subsequent sweats; venesection if systolic blood pressure is over 180 and more particularly if the diastolic pressure is high; an initial dose of veratrum viride (10 minims) followed by nitroglycerine 1/100 gr. at four-hour intervals. Puncture of membranes if pregnant or in labor and abstention from any operative interference to hasten delivery, which was found to spontaneously terminate in from eight to ten hours from the institution of treatment.—*American Journal of Obstetrics.*

Easily Procured Hot Compresses.—Elizabeth Robertson suggests to wet the compress with tepid water, then iron it rapidly with a very hot flatiron. Sufficient steam is produced to hold more heat and the hands are protected from wringing out excessively hot cloths.—*American Journal of Nursing.*

Injection Treatment of Hemorrhoids.—A 20 per cent. solution of carbolic acid in equal parts of glycerin and water injected by means of a sterilized needle into the hemorrhoids produces excellent results and removes the necessity for confinement in bed, or an anesthetic, and the risk of stricture or incontinence.

Treatment for Rhus Toxicodendron Poisoning.

℞ Resorcin, grs., xl
Pulverized starch, ʒiv
Zinc oxide, ʒiv
Lanolin, ʒiij
Vaseline, ʒvj

M. Sig.: Apply on sterilized gauze to affected area. —*Medical Summary.*

Exercise on All Fours for the Prevention of Subinvolution and Retroversion.—Beck offers this means as a prevention of these conditions after childbirth, but only to be used when the patient can have the opportunitly to rest for nine days after the delivery. On the ninth day after labor the patient is required to walk five or six yards on her hands and feet with the knees held as rigidly as possible; on the next day the distance is doubled and the exercise is to be carried out both morning and afternoon. The walk is increased gradually each day until discharge from the hospital, and the patient is advised to continue the maximum walk at home for two more weeks. Any abnormal condition, such as a bloody vaginal discharge, contraindicates this exercise.—*American Journal of Obstetrics.*

A TUBERCULOSIS SURVEY OF AN ALASKA ESKIMO VILLAGE.

USING CHILDREN UNDER THE AGE OF 15 YEARS AS AN INDEX.

BY H. CLAY MICHIE, B.S., M.D.,
CAPTAIN MEDICAL CORPS, U. S. ARMY.

THERE is no disease that has received more attention than tuberculosis, and there is no disease that demands more investigation on account of its high morbidity and mortality rates. It has been said that one-seventh of the total deaths of the world are due to this disease. One-seventh is too low an estimate in this portion of Alaska.

No one knows when or how tuberculosis was introduced into Alaska, but it is most probable that it was brought from Asia with the aboriginal tribes. It is possible to obtain a history of pain in the chest, emaciation, spitting blood, and "a long time sick" in a tribe as far back as memory goes; but as there are no records, except the totem poles, history dates no farther back than the memory of man. These totem poles are records of family deeds and achievements, as killing a certain kind of an animal, etc., and are not health records.

The specific cause of tuberculosis, of course, is known to all professional men, but we know of no specific treatment. When these conditions exist we lay great stress on the predisposing causes to disease and must rely on Nature for the therapy. In both of these respects the Eskimo is unfortunate. He is predisposed to tuberculosis from every aspect, his ancestors have had it and most of his children are now suffering with it. The natives live together in small houses made of mud, logs, grass, or anything they can get, averaging about 350 cubic feet of air space per person. Some of these houses are partly underground as illustrated in Fig. 1, from a drawing of an Eskimo "igloo" of the Yukon Delta. If they live near any trading station they will have a glass window; if not, they will have a small opening over which is stretched a translucent curtain made by sewing together several strips of seal gut after it has been scraped and dried.

Fuel is scarce; in fact, there is not a tree within 50 miles of here, and the Indian must rely upon gathering driftwood from the seashore. As it is so hard to obtain fuel, and he never provides his winter supply of fuel during summer, he exerts every effort to keep within his walls all the heat generated by the small amount of wood consumed. With this in view you will find that every possible opening has been closed and will be kept closed, and that his house is a very small one indeed. The house is usually composed of one room and a storm entrance. Within these the Indian stores everything he has except his means of transportation—kyak, dogs, and sleigh. He dresses principally in furs. These have been poorly tanned and are foul smelling (old urine has been used in the tanning). He sleeps in furs, sometimes upon improvised benches and at other times sitting upright upon the floor with his back against the wall, where he nods all night without undressing. There is no form of artificial ventilation, and there is no natural ventilation if he can prevent it; in fact, some of the Indians will even draw something over the window for fear that "spirits" will see them while they are asleep.

The white man of the United States knows very little about Eskimo food, and may not be in a position to believe a general description of it when he reads it. In fact, to get the proper conception of the Eskimo food, one must see it and smell it. The native lives almost entirely on food obtained from the water, and the villages are located on or near the sea or a stream. In spring and summer they catch fish by seining and with traps. These fish are split from head to tail and hung up to dry, and in some cases are smoked for preservation purposes. They also catch seal (the hair seal), extract the oil by boiling down the fat, and eat the meat. These two articles of food are stored in their houses, the fish in piles or bundles and the seal oil in such vessels as they have. The fish may be cooked with a little water and flour (if they have it), but are usually eaten dry and raw. The seal oil is also eaten raw. At meal time the family sits in a circle upon the floor and the squaw places a vessel of seal oil in the center, convenient to all, and gives each person a fish. They eat the fish straight, and from time to time dip three or four fingers into the seal oil up to their knuckles, then, placing their fingers in their mouths, they suck the oil off. This is repeated until the meal is completed. If any oil is left over, this is saved for another meal. This is about the most complete bath that some of their hands get, and it is not uncommon to see children with their fingers much cleaner looking than the rest of their hands on that account.

Winter offers another kind of food—tomcod fish. This is a fish with white meat, soft and comparatively free from bones. During the tomcod season the natives can be seen daily out on the ice fishing through a hole. They use a hook on a short string and stick. A piece of red flannel or some other article is used as bait. The fish are attracted to the hole by the light and by vibrations created in the water on moving the hook up and down. As they appear at the hole in the ice the native moves the hook up and down, catching the fish by the mouth, side, or anywhere. These are thrown out on the ice and rapidly freeze; are then taken home and stored in the storm shed. They are eaten raw in the frozen state. The native also eats geese, duck, reindeer,

and ptarmigan; in fact, anything obtainable. They are poor providers, and in winter many of them have to rely on the tomcod they catch daily or go hungry. At times they will catch fish or game in summer and bury it in the ground, possibly to prevent access to flies. In winter this partly or completely decomposed mass will be dug up and eaten, sometimes raw and sometimes cooked. They are said to pull off the feathers or scales with their fingers and eat the animal to the viscera.

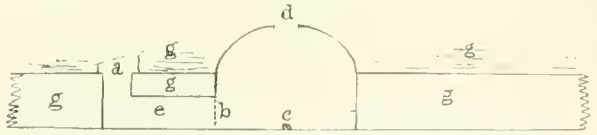

FIG. 1.—Diagram of an Eskimo Igloo of the Yukon Delta, Alaska. *a*, Entrance, covered to keep out rain and snow. *b*, Curtain of fur to prevent draughts. *c*, Fire pit. *d*, Opening in thatched roof, covered with seal gut for light, occasionally opened to let out smoke when too concentrated. *e*, Underground passage way. *g*, Ground.

Water is scarce in the native village, and the native rarely bathes. In winter all water is obtained by melting ice. The only form of bath that they freely indulge in is the "sweat bath," and this is almost entirely confined to the men. At certain times during the year—usually fall, winter, and early spring—the men gather in the kashim just after the sun goes down for the purpose of taking this bath. Each village of any size has a kashim, or council house. This is built of logs, mud, grass, etc., has no windows or doors, has an underground passageway, that opens up into the center of the room, through which the native enters. In the center of the roof there is a small opening covered with seal gut through which the small amount of light enters. Ventilation is exceedingly poor, and the walls are black from smoke. After the men enter for their bath, a smouldering fire is started in the pit through which they have entered and the smoke and heat enter the kashim. The natives are naked and seated or lying down on the benches around the sides of the kashim or upon the floor. The smoke is intense, and they cover their noses and eyes with very fine wood shavings. They must remain in the kashim until the fire is out in the pit, as this is the only means of exit. When the bath is over, the native rubs himself down or, if very hot, will go out and roll in the snow first. He often rubs himself with seal oil before dressing.

From the above insight into the Eskimo environment it is quite conceivable why any communicable disease spreads rapidly among them, why their resistance is low, why they are easy prey for epidemics, and why the odor of their person and shacks is almost unbearable (to the untrained nose).

The United States Bureau of Education has, as one of their duties in Alaska, the medical care of the Eskimo. Their appropriation is small, and they cannot reach many of the natives, and St. Michael is one of the places where no medical attention is furnished. In fact, the nearest doctor is about seven days distant. The smell of these people and their shacks, the filthy condition of their person and clothing, and the presence of head and body lice, make professional attention among them the most disagreeable duty the writer has yet encountered. In spite of the above disagreeable features, a tuberculous survey of the native villages on this portion of St. Michael Island was begun on Feb. 16, 1916, and completed about two months later. This survey consisted in going through every house, noting the size, condition, number, and age of the persons living therein, garbage and sewage disposal, and general sanitary conditions.

There are two villages at St. Michael, one composed largely of "siwashes" and the other of "squaw men." This latter village, although quite unsanitary, is far cleaner than a typical native village. The other village is composed largely of Eskimo, or siwashes, and is more nearly a typical one, but both are considered among the cleanest villages in Alaska. The native village is the one from which the following statistics are taken.

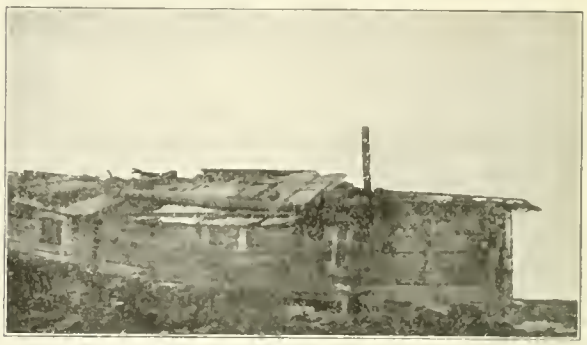

FIG. 2.—Eskimo house, one room; fourteen persons live here.

Without exception a native village is the most unsanitary place the writer has ever seen. The Eskimo depends on the malamute dog for all of his land transportation. These animals are tied outside of the house and given one fish daily for their subsistence. The site around these dogs becomes intensely filthy from urine and feces, but remains frozen until about May of each year. The native eats almost everything that is set before him, so there is little or no waste from that source, but the men urinate just outside of their doors, and the women and children urinate and defecate in such vessels as they have and throw it out of the window or door. The dogs eat the feces and the urine freezes. In spring when the snow melts and leaves all of this solid material, a native village is about the filthiest and most foul-smelling place imaginable.

There are 107 natives in the St. Michael Eskimo village, occupying 27 houses with an average of about 350 cubic feet of air space per person. Of the 107 persons, 46 are children under the age of 15 years. In fact, the absence of persons between the ages of 15 and 25 is very noticeable, and this is also true in the native villages of Sourdough and Stebbins that have recently been visited. Some persons claim this is because of an epidemic in 1900 that killed thousands of natives, and others say that it is a well-known fact among the natives that the sixteenth birthday frequently is a death period, and these people believe that if they can pass this birth-

FIG. 3.—Modern (clean?) village.

day they will grow into manhood. The origin of this belief has evidently come from the exceedingly high death rate about this age from pulmonary tuberculosis. There are 10 other persons who live in the St. Michael village a portion of their time, and many others who visit here from other villages. There is very little difference in size of the several houses, but from one to fourteen persons occupy each. In one house there are eight adults and six children. There is also advanced pulmonary tuberculosis among them, but all live and eat under the same conditions.

Realizing the difficulties of going into the houses of these ignorant, dirty, and superstitious people to make physical examinations, it was thought best to turn to the schools and use these children as an index. It has been said that once we contract tuberculosis, the tuberculous lesion remains, although possibly presenting no symptoms but remaining in a walled off state.

There are two schools at St. Michael, one "The Native School" which native children attend, the other, "The White School" for white children, but which a few other children who have Eskimo blood attend. These latter children live under conditions more nearly approximating those of white people. The cooperation of the several teachers was requested, and the teachers in both schools brought their pupils to the office, where they were examined physically. The von Pirquet tuberculin test was made on each (using Koch's O. T.) and read the following day. An attempt was made to examine the sputum from each child, but was discontinued as unsatisfactory except where the child had a cough.

Of the 46 children in the village, 26 were examined and tabulated as below. A greater number could not be obtained without arousing antagonism, as in some instances the parents were afraid to let their children be examined.

*T. B.=Tubercle bacillus. M.C.T.=Micrococcus tetragenus

Eight children were examined from the "white school," and the results from this examination were as follows:

This is a small number, and one should not draw the conclusion that these figures represent conditions all over Alaska for children under the age of 15, but it does give an insight into what exists in the schools here.

Comparison

	White School, per Cent.	Native School, per Cent.
Positive	62 5	61 53
Negative	12 5	23 05
Suspicious	25.0	15.36

There was occasion to examine 11 adults during this survey, both the sputum and their physical condition. All were positive for tuberculosis. However, all of them asked to be examined on account of pain in their chest, and some on account of hemorrhage.

It is believed that at least one-half of the suspicious cases in the tables above would prove to be positive if several examinations were made. In the above tables, cases are called positive when they presented positive signs with the stethoscope and a positive tuberculin test; are called negative when neither of the above were present, and suspicious when abnormal lung signs were revealed and the tuberculin test was negative or inconclusive.

The following method was found most satisfactory in applying the tuberculin. The jeweler's swivel screw drivers are placed in 95 per cent. alcohol for sterilizing purposes; the left arm is scrubbed with alcohol just below the insertion of the deltoid muscle. The operator seizes the fleshy portion of the under surface of the patient's arm and draws the skin taut, then with a 4½-in. screwdriver, as shown in the accompanying illustration with the swivel in the palm of the hand, rapidly turn the bit in first one direction and then the other until the epidermis is removed and the true skin exposed. This will take about six half turns, make a beautiful scarification, and cause little or no pain. The denuding of two areas is invariably done, the upper used as a control with nothing applied and the tuberculin applied to the lower with a flamed platinum loop. No dressing is used, and the patient reposits the clothing as soon as the tuberculin is dry. The patient returns in 24 hours and a comparison is made of the two lesions. The control shows little or no irritation, only a dry scab. If negative, the lower lesion will resemble the upper; if positive there will be a red papule at the lower lesion surrounded by a hyperemic zone. Depending upon the size of the papule and the hyperemic zone, the table includes one, two, or three plus indicating the degree of positiveness.

Sputum examinations were made in thirteen of the twenty-six cases from the Native School, and the tubercle bacillus was found in three of the thirteen. These three cases had consolidated areas, many rales, cough, and sputum; also presented a phthisical appearance. A careful search was made

for the *Micrococcus tetragenus* in all of the sputums examined, and this organism was found in six of the thirteen. The relation to the tuberculin reaction can be seen on the accompanying chart.

The micrococcus has been spoken of as often being an associate with the tubercle bacillus, and from a limited experience the writer considers a sputum more suspicious when it contains this organism. All professional men know that the finding of even one tubercle bacillus diagnoses the specimen as positive for tuberculosis, but there are many artifacts that unavoidably appear in microscopic specimens, and the writer would not call a specimen positive on finding only one object that appeared to be the tubercle bacillus. It has further been the case in my experience that one will not find only one tubercle bacillus. If this organism is present, and the preparation is properly made, a search for half an hour will reveal a number of them or none at all. However, this may not be the experience of men more experienced in microscopy.

As the tuberculous percentage is high in this

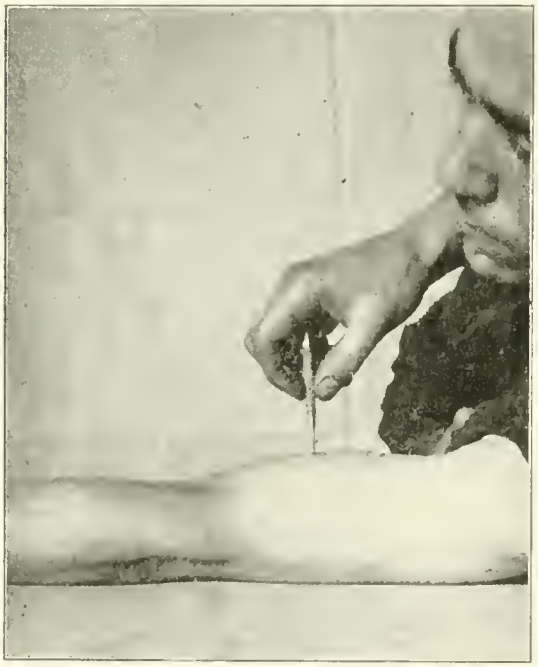

Fig. 4.—Method of administering tuberculin with a swivel screwdriver.

locality, a medical man practising here will necessarily make many sputum examinations. The following is the procedure that has been followed in this laboratory: The patient is instructed to collect what is coughed up and not saliva, and is given a paper sputum cup for this purpose along with a metal frame to hold it. When the specimen is brought in, the paper cup is removed from the frame and opened. Suspicious particles are smeared evenly and thinly on clean glass slides free from scratches, the specimen is dried in the air and passed through an alcohol flame 7 to 10 times, depending upon the thickness of the slide, to fix it. The slide is given a number which corresponds to the sputum cup and the smear outlined with a wax pencil so as to prevent the stain from spreading over the ends of the slide. Four slides are made from each specimen of sputum, and all are given the same number. These slides are placed upon a level rack that has an opening under each slide. More slides are made in a similar manner until all the specimens are ready for staining. Alcohol carbol fuchsin (alcohol 95 per cent., 20; phenol crystals, 8; fuchsin, 4; water, 100) in definite amounts, as indicated upon a glass tube used for the purpose, is placed on each slide. This completely covers the specimen between the parallel pencil marks and does not flow upon the ends of the slide. After each slide is covered, an alcohol flame is passed under the slides until they commence to steam and are left steaming (not boiling) three minutes, care being taken to see that none of the slides becomes dry. Wash with water, commencing with the first slide stained, drain off the excess and decolorize with acid alcohol (hydrochloric acid, 2; alcohol 95 per cent., 98) until there is no red color left; wash and stain three minutes with Loeffler's methylene blue; wash, dry, and examine.

Summary:—1. More than 61.5 per cent. of the Eskimo children under the age of 15 years are tuberculous in one of Alaska's cleanest villages.

2. Their environment is such that tuberculosis must increase among these people.

3. They offer one of the greatest fields for medical missionary work.

4. From a hygienic standpoint their entire system of living is wrong, but will ignorance, superstition, and climatic conditions permit a change?

5. The only source of relief at present seems to be the enactment of the necessary legislation to prevent fur traders from robbing the Eckimo of his small products, and larger medical appropriations to the Bureau of Education for use in Alaska.

THE PRESENT STATUS OF CHRONIC MULTIPLE ARTHRITIS, WITH SPECIAL CONSIDERATION OF INFECTION AS AN ETIOLOGICAL FACTOR.

By GEORGE R. ELLIOTT, M.D.,

NEW YORK.

ASSISTANT PROFESSOR OF CLINICAL ORTHOPEDIC SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, N. Y.; ATTENDING ORTHOPEDIC SURGEON, MONTEFIORE HOME AND HOSPITAL; ST. FRANCIS AND ST. JOSEPH HOSPITALS; MEMBER OF THE AMERICAN ORTHOPEDIC ASSOCIATION.

In a former paper we spoke of the proliferating or ankylotic type of chronic multiple arthritis in which the rôle of infection is evident; in the present we shall consider the non-ankylotic type in which infection is doubtful.

Degenerative or Non-ankylotic Type of Chronic Multiple Arthritis.—This type, by some designated osteoarthritis, hypertrophic arthritis, is characterized by degenerative joint changes and new bone formation. It occurs chiefly in middle life. There is slight, if any, tendency to ankylosis. It is attended with little muscular wasting.

The prominent primary lesion here is cartilage degeneration. In the proliferative type the cartilage is destroyed by a pannus formation creeping over it and gradually absorbing it, leading to fibrous tissue formation and bony ankylosis. In the degenerative type the cartilage is also destroyed but by a primary necrosis, leaving the ends of the bones free. Friction of the exposed ends leads to condensation—the so-called eburnation. Ankylosis does not occur. We meet here no new cell proliferation as in the other type; in short no inflammatory findings. We have the melting away of certain tissues with excessive new bone formation. Pathologically, a true degenerative process on the one hand with a slow heaping up of new bone on the other. Of the small joints, the distal phalangeal joints are the first to

be attacked in contradistinction to the proliferative type, where the proximomedial joints are first implicated. This clinical onset is striking and bespeaks the strongest possible differentiation of the two types.

Fig. 1.—Degenerative or non-ankylotic type of chronic multiple arthritis. Onset at menopause. Note the enlarged distal joints—Heberden nodes showing well. Note also proximo-medial enlarged joint—a later manifestation of the disease.

The subjects are older and many writers are fond of using the term senile — at present a word of doubtful scientific pathological meaning. This type is exceedingly common at the menopause.

There is a disposition on the part of some to regard the type as primarily due to bacterial infection. At present we have no scientific basis for such a sweeping belief. Its exponents produce no scientific proof. Infection does not appear to explain this type as it does the proliferative. Most of the signs of infection here are wanting. There is an abscence of fever, little or no glandular enlargement, little or no leucocytosis—in short, there are no true inflammatory signs as in the other type. Absorption and apposition here go hand in hand, but the absorption is here due to degenerative changes leaving the bones bare. These are ground into condensed surface formation through friction changes much as rocks are ground through glacier movement. In the proliferative type the cartliage also disappears but disappears through a live fungus-like pannus eating into its very substance, absorbing it and leaving in its place new granular tissue which becomes fibrillated, going on to true bony ankylosis. Here then is the real pathological difference and this alone is enough to stamp the types and explain much of the clinical difference. New bone formation seems to develop secondarily, the result of stimulation of the osteogenetic cells. The acting irritation comes from cartilage loss influenced by trauma and static conditions.

To make the subject clear and to accentuate the striking clinical characteristics arising from the pathology just considered, let me mention the so-called Heberden-node type as perhaps the most classical illustration of the disease under consideration. The distal phalangeal joints are here first involved and as an early sequel to cartilage loss there follows a new bone formation on the distal phalanges. This node contrasts with the spindle-shaped or Haygarth nodosity of the proximomedial phalangeal joints so characteristic of the proliferative type. This degenerative malady advances usually through repeated slightly painful attacks in the vicinity of the node and after the subsidence of these attacks the node is found larger.

The malady, if unchecked, does not remain limited, but gradually extends to the more proximal joints of the hands and to other joints of the body. Sometimes this disease makes its first appearance in one of the large joints as the knee or hip.

The cuts reproduced here well illustrate this type of arthritis. They are after photographs of a private patient, whose condition I have studied very thoroughly.

This disease began at the menopause but intermittently involving the distal phalanges and the patient began to point to the "knobs" on her fingers.

Fig. 2.—Radiogram of hand shown in Fig. 1. Note involvement of distal joints, also proximo-medial joint of little finger—cartilage destruction and new bone formation. Note good condition of remaining joints. Compare with radiagrams of proliferative types shown in a former article, noting especially selective character of each.

After several years the medioproximal joints of the hands became involved together with the tarsal joints of the feet. For the benefit of those practitioners who in similar cases are wont to cut out meat from the diet, I will say that this patient's

diet was during all the developmental period of the malady almost entirely carbohydrate. Meat had early been excluded.

If we study the *x*-ray picture of the hand and foot here produced, we fail to find the wholesale bone destruction so characteristic of advanced cases of the proliferative type. This wholesale destruction in the latter type led to its formerly being called atrophic type—a term now largely given up. I may say here that many confound the terms proliferative and atrophic as applied to the same type—contradictory terms apparently. The explanation lies here: The term atrophic arose in the classification of the early clinicians through finding the large bone destruction in advanced cases; this, together with marked muscular atrophy, made up much of the picture. The word proliferative applies to the early stage of the disease and refers chiefly to the soft tissue cell formation affecting the synovial membrane and capsule—a real increase stamping the type proliferative. The late extensive bone destruction or wholesale bone atrophy or late atrophy term is giving way to a term expressing the early pathological process of proliferation. We may also here refer to the type we are considering as by some still designated hypertrophic from finding excessive new bone formation. This term is still used a great deal but is gradually giving way to the term degenerative or non-ankylotic.

We have shown[1] that new bone formation alone is unreliable as a diagnostic factor since it may go with any form of arthritis where the osteogenetic cells have been exposed to prolonged irritation.

If we revert then to a careful study of the radiogram of the hand as shown in the cut, we do not find the great bone destruction—and the cut represents an advanced case — characteristic of advanced types of the proliferative, ankylosing, or if you please, the atrophic type. The apparent wholesale bone destruction is largely due to new marginal bone formation deepening the joint cavity giving the appearance of bone destruction. This is not unlike the findings often characterizing arthritis urica joints. I called attention to this in a paper[3] read before the American Orthopedic Association showing the actual specimens dissected and well illustrating just what is said here.

I wish to say that while extensive bone destruction is especially common in late stages of the proliferative type of arthritis and condensation and new bone in the degenerative type and in the arthritis urica type, yet extensive bone destruction does sometimes occur in the latter two types. Its explanation may sometimes be found in extensive arteriosclerosis or to a deposit of calcareous salts in the blood-vessels leading to tissue loss, much as a cerebral thrombosis leads to a brain loss.

As already said, this type of arthritis often invades the large joints. We frequently see it affecting the knees, especially of women. Again, the familiar time of onset is at the menopause. Here again we have the primary cartilage loss through degeneration accompanied with formation of new bone. Characterizing this are the subjective symptoms of pain, stiffness, and disability, and the objective signs of grating, irregular swelling, and often evidence of small loose detatched particles. The so-called malum coxæ senile is another form of the malady under consideration. This degenerative type is also very common in domestic animals, especially in old age. Diabetes is not infrequently associated with it.

What Is the Primary Etiology Accounting for This Degenerative Type?—We have spoken of cartilage loss as being primary. Strictly speaking it is secondary. In the sense we use the term is meant that cartilage loss is the first objective sign of the malady. What causes the cartilage to degenerate?

We feel that enough has been said to show that those who would regard true bacterial infection as the basis of this malady are confronted with findings markedly in contrast with those characterizing the proliferative type. The picture is not at all one of infection. All the ear marks of true bacterial infection are wanting. We refer to the true streptococcal infection or of its mutants or variants or to infectious disease proper.

It is unfortunate that many writers on true bacterial arthritic studies still stick to the general title arthritis deformans, making no real differentiation. At this time it bespeaks a lack of knowledge of the subject. Even Rosenow has been justly criticised for his lack of differentiation. His bacterial studies, I am safe in stating, have not yielded in the degenerative type of arthritis now under consideration any of the valuable findings he has given us elsewhere. He is only one of many using the term arthritis deformans in a loose way.

At the basis of the primary etiology there is much pointing to the working of some chemical rather than true infective factor.

As stated, if we study the joint changes we find much reminding us of the joint changes characterizing the arthritis urica or gouty type. There are cartilage loss, eburnation, new-bone formation. In fact findings which characterize that type less the tophaceous deposits of biurate of soda. Many writers recognize in this type a certain relationship with the arthritis urica type, and believe the underlying cause due to a faulty physiology rather than to true infection—a chemical rather than a bacterial factor. It must be admitted that at the present time we do not know just what gout is. We do know, however, that it expresses itself to us through an abnormal prominence of uric-acid findings, while in the degenerative type no such abnormal prominence of uric acid is found. This is a point for physicians to bear in mind.

Axhausen, an active worker in the arthritic field, believes cartilage loss to be the primary factor explaining the changes found in chronic multiple arthritis. We purposely omitted referring to Axhausen's view while considering the proliferative type believing that his findings have a closer relationship with the degenerative type we are now considering. What he says of cartilage loss is of great interest here.

Axhausen[5] contends that from the clinical and macroscopial consideration of chronic multiple arthritis it is impossible to expect a solution of the problem and turns to the histological picture. He places the focus of total anatomical and histological changes in primary cartilaginous necrosis, and holds that the cartilage loss leads, in accordance with laws, to reactive phenomena in the neighborhood which anatomically and histologically make the clinical picture of chronic multiple arthritis. He says the idea that bone necrosis is always identified with infection and sequestration is incorrect, that there is a simple bone necrosis without infection and sequestration playing an important rôle in bone pathology; that from whatever cause—bone transplantation, fracture, bone tumor, or bone syphilis—wherever bony necrosis exists, is established a pow-

erful irritation upon surrounding ossification tissues producing swelling and new-bone formation. He experimented with normal knee joints of dogs and produced circumscribed cartilage necrosis by destroying portions of cartilage varying from the size of a lentil to that of a small bean, and made his examinations after longer and longer periods.

Beneath the cartilage loss he found the medullary tissue changed to fibrous tissue and under the working of this tissue resorption and dissection in progress, also sclerosis of the bone. He also found cystic spaces, synovial villi, and marginal bone osteophytes—in short, all the changes seen in chronic multiple arthritis.

Axhausen reminds us of the fact that cartilage is nourished through diffusion and that the diminished nutrition of advancing years may lead to superficial and even deep cartilage degeneration. He also refers to Weichselbaum's demonstration that a degeneration, even to necrosis of the superficial cartilage cells, belongs to the physiological changes of age. Axhausen believes that if such changes increase and produce a deep car-

Fig. 3.—Right foot of patient whose hand is shown in Fig. 1; degenerative or non-ankylotic arthritis. Note new bone formation (shown by arrows) involving tarsus. Process identical with that shown in hands—cartilage loss and new bone formation.

tilage necrosis, then we have a pronounced picture of chronic multiple arthritis, and says that Weichselbaum, through anatomical relationship, has established in arthitis deformans none other than a high grade of simple senile change; that where nutrition has been interfered with we must recognize many factors—trauma, acute joint inflammation, constitutional general disease, senium. The binding factor in all these cases is cartilage necrosis. Not all of the changes Axhausen describes as resulting from his experiments are found in the degenerative form of arthritis. I refer especially to the fibrous tissue formation.

Von Manteuffel produced artificial sclerosis of the vessels through freezing and congestion, and he claims[8] as a result of his experiments final complete disappearance of the cartilage and of the entire joint with connective tissue ankylosis of the two bones.

The connective tissue formation and ankylosis, as we have said, are not present in the degenerative type now under discussion. We are led to ask how far we can accept the experimental destruction of normal joint cartilage as the equivalent of its loss through disease. Is not the reaction to destruction of normal cartilage through operative procedure quite different from the reaction incident to degenerative conditions? To the pathologist there is a wide difference and we do not believe such experiments will ever give the true picture. At present it is safe to adhere to the pathology of Nichols and Richardson,[9] which we have followed and which is being generally accepted.

Much that we have just considered is placed by the French school of medicine under the term chronic rheumatism of toxic or dyscrasic origin (gouty rheumatism but not true gout), and Ott accepted this in a report to the fifteenth Congress of German Physicians. From the point of treatment he classified it as due to general nutritional disturbance—to an excessive acid production in the system. This variety is well described by Teissier and Roque.[4]

Teissier says it is not true gout, there is no tophus, it is not hereditary as gout, but acquired —an acquired uricemia. He further says that (1) sometimes this uricemia is created by clogging of the skin under the influence of damp cold; (2) sometimes it is the result of prolonged digestive disturbances, and (3) sometimes it is secondary to renal insufficiency. But he admits that this does not explain difference between this and gout, *i.e.* between an hereditary uricemia and an acquired uricemia. The French authors generaly recognize a casual relationship between the type of arthritis under discussion and a series of dyspepsias—the so-called acid dyscrasia.

All signs point to the gastrointestinal tract as playing a large rôle here. The intestinal rôle differs much from the part it plays in the proliferative type. Its rôle there is that of a septic focus, such as foci lodged in the appendix, gall-bladder, etc., while in the degenerative type it appears to be some direct absorption from the tract proper. This is said with full knowledge of the fact that many leading thinkers are placing the real starting point of arthritic urica in the alimentary canal —a probable catarrhal condition of the mucosa of bacterial origin. In the degenerative type of arthritis faulty physiology of the intestinal tract leading to deleterious absorption does seem to play a large rôle. Clinically I have seen over and over again outbreaks of painful joints with increase in size associated with gastrointestinal disturbance characterized by marked indicanuria and faulty acid conditions, the attack subsiding promptly upon correction of the digestive disturbance.

There remains only to be worked out what kind of absorption takes place. Is it some toxin or a true intestinal infection of bacterial origin? If bacterial, we cannot think of it in the same line of bacterial infection which we fully considered under proliferative arthritis. The studies of Adami already referred to are worthy of consideration here.

Elimination in this class of cases also plays an important rôle. We have referred to the frequency of this type of disease in women at the menopause. We know at this time in many women there are great disturbances leading to faulty elimination. The systemic equilibrium is upset. The individual for years has through her twenty-eight-day habit been getting rid of material and now the system must readjust itself. At this stage we often see starting up the joint changes under consideration.

We shall only allude to the vast amount of work done on calcium in connection with this period. The subject is still to be worked out. But the great frequency of this type of disease developing with the menopause is certainly suggestive and must be considered in the treatment of our patients. We are here reminded of Aphorism No. 29 of Hippocrates: "A woman does not take gout unless her menses be stopped." The old fellow may have mistaken Heberden nodes and boggy stiff knees for gout. Many modern physicians do the same thing. The modern physician may be right. Heberden, himself a gout specialist, expressed the view that the node described by him did not mean gout. Charcot taught the same, pointing to the large number in the Salpêtrière—200 out of 400 old women. As stated, many physicians believe that there is some relationship; this I have already brought out. Llewelen Jones regards the node as a senile dystrophy independent of rheumatism or gout. Léri examined 30 patients afflicted with chronic rheumatism, as the term is used by the French, and found that seventeen had Heberden nodes. I may say the belief that the true Heberden node is in some way allied with gout is growing. Supporting this view I may mention Begbie, Hilton Fagge, Lecorshi, Dyce Dukworth, Archibald Garrod.

There is much to show that a node may appear on the distal phalanx, largely due to trauma, and remain in statu quo for many years. But the type we are considering and well illustrated in the cut (Fig. 1) is certainly an entity, and while it is not expressed through deposits of biurate of soda, characteristic of gout proper, there is much showing relationship with an allied condition. Whatever our future studies may disclose as the primary cause of this degenerative type of arthritis, and we believe it will be found to be something besides senility, we feel sure in stating that it stamps a type of its own and has nothing to do with infection in the strict bacterial sense. We have here a clean-cut picture, if not a specific disease entity, a true pathological condition with characteristic showings.

True Infectious Arthritis.—In this, the arthritis of certain well-known infectious diseases, we have a direct cause explaining many cases of arthritis. Let me mention arthritis complicating pneumonia, gonorrhea, typhoid fever. In acute arthritis of this kind it is reasonable to expect that the specific organism of the disease giving rise to the arthritis may be present in the joint. This has often been verified, as in gonorrhea, for example. The onset is usually sudden and the signs are inflammatory in character. It is possible that the activity of the organism may be severe enough to be pus-producing.

Another type of arthritis, however, may complicate these infectious diseases, not so acute, but of a chronic character. It is this latter type that chiefly concerns us in our study of chronic multiple arthritis. The arthritis of gonorrhea well illustrates what I am saying. I can do no better than to quote from Brackett[7] at this time. In his paper on arthritis associated with lesions of the genito-urinary tract Brackett refers to the two types of gonococcal infection: "One usually monarticular, in which there is a direct bacterial invasion of the joint characterized by an arthritis of sudden appearance with evidence of inflammatory involvement; and a second type, polyarticular and of a mildly inflammatory character, slowly damaging the joint from toxic infection. This latter type may develop with an entirely quiescent external urethral condition." You will recall here the writings of the urologists on the part played in multiple arthritis by vesicular foci, writings in number exceeded only by those of our dental confrères. The term toxic infection used by Brackett as the factor of the second type has yet to be cleared up. It may be that this toxic infection will be found to be a mutant or variant of the gonococcus in keeping with the teaching of the transmutationists fully discussed under the heading proliferative arthritis.

If we study the arthritis of all the class of infectious diseases now under discussion, we shall find the dual expression so characteristic of the arthritis of gonorrhea also more or less characteristic of all. It is the second or chronic form of infection that chiefly concerns us here. Both acute and chronic arthritis do not necessarily manifest themselves in the same patient. For example, in gonorrheic arthritis we may meet with the acute form only—the direct bacterial invasion. In the absence of focal points of storage, as the seminal vesicles, for instance, no points of chronic focal infection existed. Again the acute form is wanting and only the polyarticular manifests itself. I believe this is often true in both gonorrhea and syphilis.

We see, then, opening up a rational explanation of a great deal of chronic articular disease. At the present time, excepting tuberculosis, it is difficult to diagnosticate these chronic types and say what organism has been acting. Such types of arthritis are apt to be irregular. At the present we believe their external expression differs materially from either of the main types already fully discussed.

In the infectious forms of chronic multiple arthritis spinal involvement is common; note its frequency following gonorrhea and typhoid fever, for instance. In the proliferative type, where so many of the joints become implicated, the vertebral column usually escapes. In an examination of extensive polyarticular bed-ridden patients affected with the proliferative type, the spinal column generally gives striking evidence of mobility, and usually remains unaffected to the end.

Factors Influencing All Types of Arthritis.—1.—Trauma. This factor is best seen when pain is not severe. The proliferative type is apt to be painful, compelling disuse on the part of the patient and thus escaping external trauma and the spindle-formed nodosities so characteristic of this type develop with great regularity. There is, however, also trauma of the deformity a constantly acting factor in this type causing many irregularities—contractures and dislocations, for example. It is chiefly in the degenerative type, the slightly painful type, where we see the result of external trauma. This is the result of the painless form allowing more use. This is well illustrated, usually by the index and thimble fingers in cases of this degenerative or nonankylotic type. See the little and index finger in Fig. 1.

2.—Static Conditions. Some investigators have gone so far as to put changed static conditions as a chief factor for a great deal of chronic multiple arthritis; their place in chronic multiple arthritis is now well understood. The explanation of certain findings rests upon Wolff's law, that all prolonged alteration of the function of any part of the body, either congenital or acquired, is surely followed by anatomical change. If one leg is shorter

than the other certain joints suffer through anatomical change. If a person is knock-kneed or bow-legged certain changes are set up in the knee joints chiefly. If there is hallux valgus the cartilage of the metatarsophalangeal joint of the big toe suffers. The pathological changes following static changes are apt to be allied with those spoken of while discussing the degenerative type of arthiritis —cartilage loss and new bone formation. The latter is often striking. Lane some years ago was among the first to call attention to these static results. More recently Preiser worked them out with great thoroughness.

Wear and tear, spoken of by McCrae we believe, comes logically under this head. McCrae[8] refers to the weight of the patient as a factor in influencing his own joints; this becomes a marked factor after degeneration begins.

Joint Arthropathies.—We will briefly refer here to certain arthritic conditions complicating certain organic nervous diseases—arthritis of locomotor ataxia and syringomyelia, for example. By some the former is considered as syphilitic joint disease. Such grave trophic changes do not appear to warrant a place in a paper such as this where we endeavor to restrict ourselves to consideration of chronic arthritis proper. We can scarcely think of a Charcot knee as a good example of syphilitic arthritis. It is but one of the very many manifestations of syphilis, but it is not a true arthritis.

Working Classification.—How far then are we in a position to get a mental concept of chronic arthritis? What kind of a classification are we warranted in making? In other words, what does the present status of chronic multiple arthritis teach us as a basis of classification? All sorts of classifications have been made, based on anatomical, pathological, and clinical grounds, and new classifications are constantly being given us. Many of these are erudite at first sight, but upon analysis fall by the wayside, for clinicians are unable to verify and make any practical use of them. At the present time I think it is impossible to classify chronic arthritis except under striking types. The endeavor has been made to do this in this paper. In other words, we have endeavored to fall back to a simple classification, which is in part a classification of some of the older clinicians but one now better understood and more thoroughly worked out and restricted.

1.—Proliferative or Ankylotic Type. We have endeavored to show that this type has well-defined characteristics due to infection of a modified kind. It is a real *disease entity*—the true progressive multiple arthritis, and the diagnosis should always be made. Its clinical expression is clean cut and well defined.

2.—Degenerative or Non-Ankylotic Type. This includes a large class of cases giving striking clinical pictures. This is not so much a disease entity as the former, but a secondary joint condition. The word arthrosis may be found to express this type better than arthritis. While not a distinct disease entity in the proper sense it is, however, a striking clinical type with characteristic manifestations and the diagnosis should readily be made.

3.—True Infectious Arthritis. The arthritis of infectious diseases where the joint organism is rather definitely known and sometimes recovered from the joint. The chronic types here are apt to be irregular. Diagnosis, as a rule, is more difficult, but a careful study of the history and patient often brings out a true etiological diagnosis.

4.—Mixed Types. One type, for example, may be engrafted upon another. The degenerative type may be engrafted upon the proliferative, to a certain extent complicating the picture. Léri brought this out in his discussion of the Heberden node under the head chronic rheumatism. The term chronic rheumatism is a favorite term of the French and with them covers a wide field. It is not uncommon to find evidence of the degenerative type engrafted upon the proliferative, the latter affecting the patient earlier in life and the degenerative engrafted upon this later in life. This fact is in itself a strong argument to show that the etiology of the two types is entirely distinct. Again, all types being influenced through static influences, give many irregular pictures which may or may not come logically under this mixed type heading.

5.—Arthritis Urica Type. This is chiefly characterized by the deposit of biurate of soda.

6.—Tuberculous Type. I give tuberculosis a special head rather than classify it under infectious diseases, since we are familiar with its arthritic forms. I may say that the so-called tuberculous rheumatism or Poncet's disease does not give any external characteristic picture and there is no likelihood that it ever will, since it is not an expression of a tuberculous lesion proper. It is rather an expression of a tuberculous toxemia, at present not fully understood.

The future will doubtless compel us to give special heads to certain other diseases which at present we are compelled to leave under the general infectious type. As the hydra-headed showings of tuberculosis looked upon by clinicians formerly as different diseases cleared up, so the general subject of arthritis is now clearing up. Certain well-known diseases will yield to us as well-defined joint pictures as tuberculosis has already done. This, I believe, will be especially true of syphilis and gonorrhea. So of typhoid fever, pneumonia, and other infectious diseases. I refer to the chronic polyarticular types of these maladies.

The French writers, as the result of deep study of this arthritic subject, have adopted simple classifications. One of Desternes illustrates this: (1) les rheumatismes dits d'infection, (2) les rheumatismes dits dyscrasiques, (3) les rheumatismes dits deformant progresif.

Under the latter, or progressive deforming, Desternes has followed the French school in including many forms that we believe belong in the degenerative type. Differences in etiology and deforming characteristics make for such differentiation. It must always be borne in mind that the French use the term chronic rheumatism for the great general head.

I repeat that it is impossible to follow complex classifications. I have spent many a weary hour trying to comprehend such, only to find that I was chasing some will o' the wisp. The more I study the subject the more I find the classification becoming simple. Simplicity is coming as a result of study of the arthritic problem as it always comes with knowledge of any subject. In simplicity lies strength truth - Simplex sigillum Veri (Matthias Morgan

I especially urge the simple classification under the six heads I have given as a good working practical classification, feeling that at the present time we have no scientific basis for any other. Under one of these six heads I believe all the types of

chronic multiple arthritis can be placed. I have advisedly omitted the so-called traumatic arthritis as not believing it comes within the scope of this paper. Trauma as a factor has been considered.

To place the patient properly I follow in a general way the following rule: When a case of chronic multiple arthritis presents itself to study the patient; to take a careful history; age of patient at onset of the disease and character of onset and nature of progression. Has the onset occurred in the 20's and 30's or 40's and 50's? To note the objective findings. Are there true Haygarth nodosities—the real spindle-shaped joints, or are there bony outgrowths and irregularities, any Heberden nodes for example? If the latter, are they alone or engrafted upon some other condition? Is ankylosis present? To take into consideration the occupation of the patient and note effect of such; to look for any static conditions and result of such. To search for hidden focal sites, especially if our history and examination so far tend to put our patient in the proliferative type—tonsillar, appendicular, tubal, vesicular, or dental foci. Carefully to investigate the gastrointestinal tract, especially if our examination tends to place our patient in the degenerative type. To seek evidence of a former infectious disease and history of same. To look for gouty tophi or other evidences of the gouty diathesis—having a metabolic laboratory test made if the diagnosis is doubtful; to search for tuberculous evidence. To have good *x*-ray plates made. By a process of inclusion and exclusion and careful analysis the patient can be properly placed with as much certainty as the proper placing of a flower through botanical analysis. Such a placing in chronic multiple arthritis is now necessary as so much here depends upon a diagnosis. It is only through an accurate diagnosis that we are directed to the logical course of treatment of our patient.

The chronic rheumatism and uric acid doctor belongs to the past. It is necessary to analyze, properly to exclude, and properly to place the patient. Anything short of this is neglectful and deleterious to the patient, making our treatment empirical rather than scientific.

In concluding these papers, I wish to specially emphasize one observation I have tried to bring out—that after we are able to differentiate the specific type of arthritis belonging to infectious arthritis proper as well as true degenerative arthritis, we shall still have standing out clearly one great type as a distinct disease entity. I refer to the proliferative or ankylotic type—the real progressive type of chronic multiple arthritis. As I have said, its etiological factor will probably be found to be a variant or mutant of the streptococcus group. This belief seems to be the basis of the most approved teaching to-day.

Much of the work upon which the foregoing status is based is due to the facilities for study afforded me by the Montefiore Home and Hospital, New York. The large number of arthritic patients in the institution has enabled me to study clinical types with the aid of the excellent laboratory facilities, both chemical and pathological, together with the very complete *x*-ray department, all of which the directors of the institution have very fully equipped for modern scientific study. And further, I am indebted to the valuable cooperation of Dr. Wachsmann, medical director, and his staff. I wish, also, to thank Dr. S. W. Boorstein, adjunct orthopedic surgeon, for valuable services rendered.

RAGWEED POLLEN IN THE NASAL SECRETION OF HAY-FEVER CASES.

By W. SCHEPPEGRELL, A.M., M.D.,

New Orleans.

President American Hay-Fever-Prevention Association.

The direct relationship of the pollen of certain plants to hay-fever has been established in many ways. First, the commencing and disappearance of the attack with the beginning and ending of the

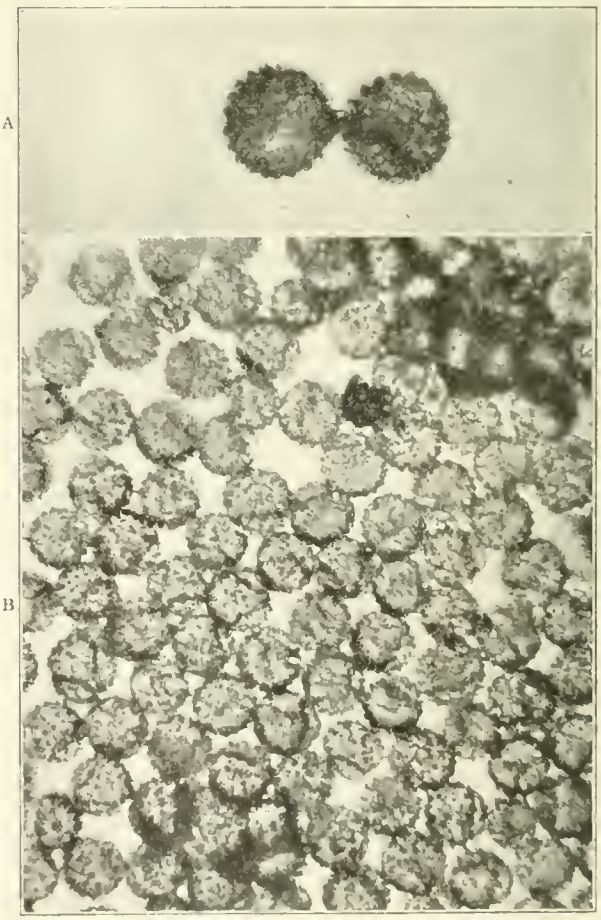

Fig. 1.—Pollen of the ragweed, × 500 diameters. The upper two (A) have a magnification of 1000 diameters. (From the biological laboratory of the American Hay-Fever Prevention Association.)

blooming of these plants. Also the development of the attack when susceptible subjects come within the potential area of the hay-fever plants. Then the confirmation by the biological tests, by means of which an attack may be induced at any season of

the year by applying a few grains of pollen to the nostrils of the subject.[1]

While these have fully established this relationship, the finding of the pollens in the nasal secretions of the patient is an important corroboration.

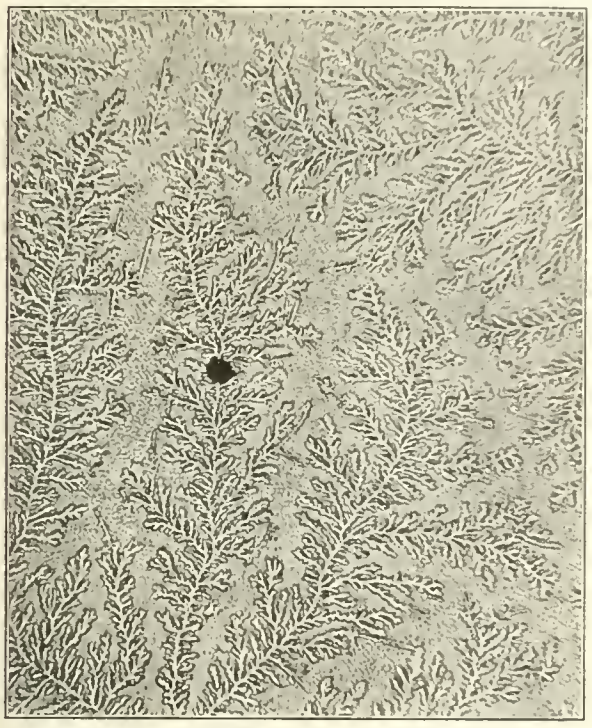

Fig. 2.—Ragweed pollen in hay-fever nasal secretion. The arborescences are salts in the secretion, crystallized in drying. × 250.

and the following report of our biological department will, therefore, be of interest.

On August 12, 1916, F. W., who suffers occasionally from hay-fever, had an attack during the night, this being due to a brisk northwest wind which blew pollen from a large area of ragweed about one-quarter mile distant. Shortly after retiring, his nostrils became obstructed so that he could continue nasal breathing only by propping up his pillows and then only through one nostril.

The following morning, when the patient arose and exercised, the nostrils became free, which was followed by the discharge of a clear, viscid mucus from the nostrils. By previous agreement, this mucus was collected and sent to our biological laboratory for testing. After the discharge of this mucus, which lasted about ten minutes, the patient was practically relieved from any further discomfort, as he left for his office which is in the central portion of the city and farther removed from the potential area of the ragweed pollens.

The mucus was divided into eight parts, each part being separately examined. The secretion was spread on microscope slides and covered with ordinary glass covers, and a drop of iodine solution injected for staining. The microscopic examination showed that there was an average of seven ragweed pollens (*Ambrosia trifida*, the *Ambrosia elatior* being very uncommon in this section) to each division, or a total of 56 pollens in the secretion collected.

The following points are to be noted in this investigation: The direct relation of the pollen to the attack, the number required to cause the reaction described, and the relief afforded by the discharge of the mucus containing the pollen.

[1]Scheppegrell, W.: Hay-Fever and Its Prevention, U. S. Public Health Reports, July 21, 1916.

It has been suggested that the irritation of hay-fever pollen might be due to the development of the germinating tubes of the pollen. In no case was there a germinating tube found among these pollens nor could the pollen be distinguished, even by the high powers, from the ordinary trifida pollen (Fig. A).

After the discharge of the mucus containing the pollen, the patient was relieved from the local irritation and developed no constitutional disturbance.

The pollens in the mucus were usually found single, but occasionally in twos and threes. A group of two magnified 1,000 diameters is shown in the accompanying photomicrograph (Fig. 1, B).

Ragwood pollen is frequently found in the nasal secretion of hay-fever subjects at our biological laboratory (Fig. 2), but this is the first instance in which practically all the pollen of an attack of hay-fever has been collected and examined.

THE SIGNIFICANCE OF INCREASED DUODENAL DILATABILITY.*

By W. HOWARD BARBER, M.D.,
NEW YORK.

There is a tendency to ascribe all duodenal dilatations to immediate constrictions, to obstructions which are frequently located at the duodenojejunal flexures. There are other factors, however, of duodenal dilatation or, more precisely, increased duodenal

Colon immediately after removal, showing markedly dilated cecum and cephalad colon following incomplete obstruction of rectum.

dilatability which are just as tangible, if not just as comprehensible, which are not resident in the duodenum, but in the terminal ileum.

*From the Laboratory of Experimental Surgery, New York University.

Increased duodenal shadows have been observed röntgenographically in individuals found to have at operations pathologically involved caudad ileums. The ileocecal regions of these individuals are commonly caught in the adhesions which apparently represent the sequelæ of acute appendicitis. The appendix is normal, not often chronically inflamed, but the end of the small gut is partially obstructed. But after this appendix is removed and the neighboring bands restricting the ileum freed, not only do the gastric emptying and the duodenal clearance improve, but the dyspeptic symptoms often disappear at the same time. Clinically, therefore, these postinflammatory bands interfere with the contractions and relaxations of the proximal as well as of the distal ends of the small gut.[1]

The question arises whether any causal relationship can be shown experimentally to exist between this form of incomplete ileac obstruction and apparent overdistensibility of the head of the duodenum.

An analogy, commonly known, is that habitual constipation gives rise, after a period of time, to increased dilatability of the cecum. Although such a cecum has been called "crepitant," large, or dilated, pathologically one is often at a loss to find anything structurally wrong with it. Furthermore, anyone may produce such a hypotonic cecum in normal dogs by tying gauze ligatures about the terminal colon so as to produce incomplete obstruction. When this obstructing band or the habitual constipation is removed, the tone of the head of the large gut improves. (See illustration.) It is logical on the same basis to expect similar disturbances with the beginning of the small intestine from inflammatory interference with the end of the ileum. To determine whether there is such an interrelation of the oral and aboral ends of the small gut, the conditions observed in humans were duplicated as far as possible in dogs. The results of these experiments have been published.[2] From this series it appeared that increased dilatability of the cephalad duodenum followed incomplete obstruction of the terminal ileum. Similar results have since been obtained on cats. (See the table.)

Table Showing Dependence of Tone of Cephalad End of Small Gut Upon Caudad End.

Animal No.	Duration of Obstruction, Days.	Dilatability of Duodenal Loop, c.c.	
		Before Ligating Colon.	After Ligating Colon.
Cat 338	14	2	2.5
Cat 339	4	1.5	2.9
Cat 344	6	1.7	2.15
Cat 324	3	3.33	3.8
	8	3.33	3.7

There appears, therefore, to be some underlying dynamic factor in increased ileac resistance that reduces the tone of the cephalad portion of the small intestine.

From these observations it seems logical, in the presence of a markedly increased duodenal shadow (as depicted by the *x*-ray during gastric emptying), to consider upon inferential grounds at least the possibility of a functionally obstructed terminal ileum.

Another association developed during the same two series of animal experiments; namely, decreased dilatability or increased tone of the oral end of the small intestine and complete obstruction of the aboral end. When the distal ileum became closed by inflammatory reaction or by fecal accumulation, the size of the duodenum decreased. The decrease in the duodenum appeared in both the dog and cat series.

The time element requires especial emphasis. In the experiments the duration of the terminal ileac obstruction was four to nine days. Traumatizing by handling or scratching the terminal ileum produced no immediate change in the tone of the duodenum so far as could be ascertained. In the humans coming under our control the time factor is usually longer. It is illuminative, however, to see that, dynamically, duodenal tone appears to be influenced by the tone of the terminal ileum.

In this light, the increased duodenal bismuth shadow does not exclusively indicate immediate obstruction, but possibly obstruction at some distal point, as in the terminal ileum.

AN INTERMAXILLARY SPLINT.

By GEORGE MORRIS DORRANCE, M.D.,
PHILADELPHIA, PA.

No special type of splint is indicated in all fractures of the upper or lower maxilla. This splint is indicated where it is impossible to obtain a swedged intermaxillary or interdental splint. As shown in the cut, it consists of a perforated plate of German silver with perpendicular sides. The sides have an opening in front, the plate being absent there to allow for an over and under bite. It is pliable so that the width between the plates can be made greater or lesser according to the width between the two sides of the jaw.

Application of Splint.—If the lower jaw is fractured, the splint is fitted to the upper maxilla and if too long is cut off. In case of fracture of the upper jaw, the splint is first applied to the lower maxilla. The sides are trimmed down or the edges bent outward, if they press against the swollen

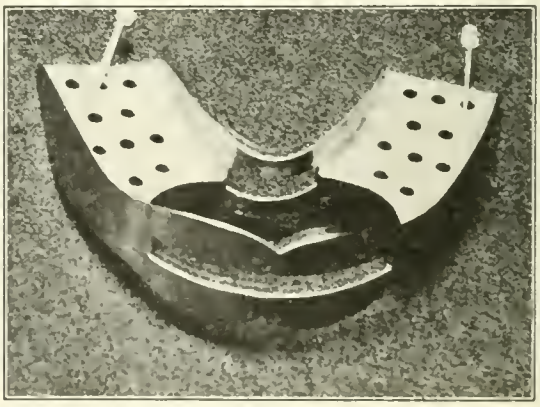

Fig. 1.—Anterior view of splint.

gums. The lower jaw is then pressed up in place to see that it articulates normally. The splint is then removed and dried. Kerr's modeling compound is softened over a flame, being careful not to burn it (it should never be softened in hot water). The

upper and lower grooves of the splint are filled to overflowing.

The plate with its contained compound is heated until the compound is softened. It is tested for heat against the patient's face; if it can be tolerated

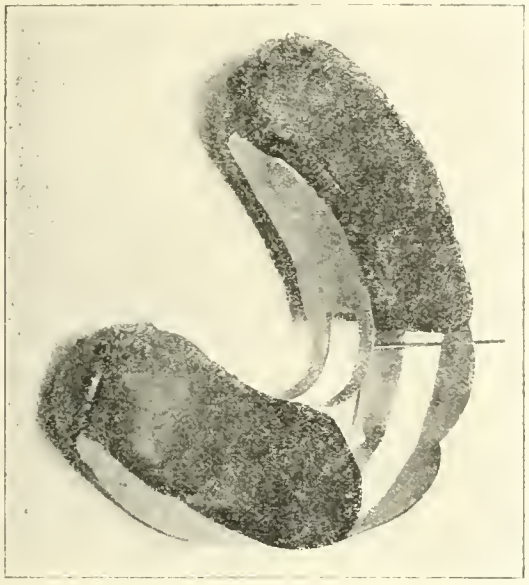

FIG. 2.—Splint filled with compound and ready for application.

against the face it will not burn the mouth. Now dry the mouth by putting in rolls of cotton and swab the teeth with alcohol. (If time permits, a hypodermic of morphine and atrophine, one-half hour before applying the splint, will help to keep the saliva in check.) Now quickly remove the cotton, introduce the splint with the hot compound and press it against the jaw. Then press the lower jaw against the upper, being sure that the normal bite

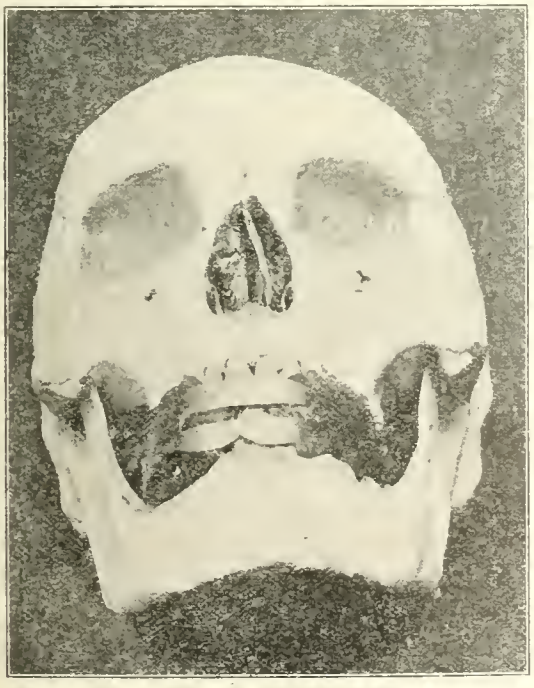

FIG. 3.—Anterior view of splint held in place by compound.

is obtained and with the first finger press the compound around the teeth. Syringe the mouth with cold water to set the compound. A Barton bandage is applied as an added security and to overcome any muscular action. The splint can be easily removed by using warm water and slight traction. The splint may be reapplied as many times as necessary, always using new compound, Kerr's being the best.

The patient is able to obtain liquids through the anterior opening and around the molar teeth. No

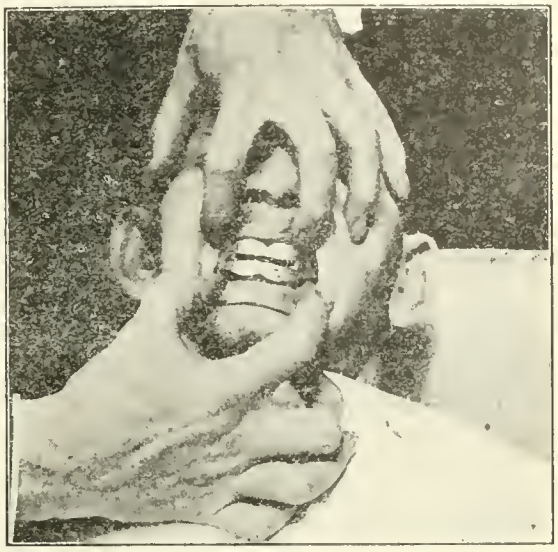

FIG. 4.—Anterior view of splint applied.

hot liquids should be allowed. Wash and syringe the mouth several times a day with permanganate of potassium or a saturated solution of potassium chlorate. Always remember the splint will hold the fragments where you place them, but do not expect it to reduce your fracture. This splint is applicable to all fractures of the jaws within the alignment of the teeth, angle, or ramus. Be sure the normal bite is obtained.

I am indebted to Dr. A. deWitt Gritman for valuable suggestions and to Mr. Dutcher, a student of dentistry in the University of Pennsylvania, for numerous modifications and the making of the first splint.

2025 WALNUT STREET.

AN APPARATUS FOR THE DIRECT AND CONTINUOUS TRANSFUSION OF BLOOD.*

BY ALFRED KAHN, M.D.

NEW YORK.

THE transfusion of blood by the syringe method for practical purposes in most cases seems to be more popular within the last few years than the cannula method as practised by Sweet, Crile, and others. The syringe method recently improved by Libman requires the use of a number of syringes. The donor is placed on one side of the operator and the recipient on the other. The blood is drawn from the donor, transferred to an assistant, who injects this blood into the receiver. The syringe is then passed to a third party, who cleans it with salt solution, in order to have it ready again for the operator. Meantime the operator uses a fresh syringe, passing it along the circuit as above described. This method offers a number of disadvantages. Briefly enumerated these are: the number of syringes used, number of assistants required, chances of clotting, chances of infection, special technical knowledge required, thus making it diffi-

*From the Laboratory of Experimental Surgery, New York University and Bellevue Hospital Medical College.

cult for the average surgeon to practise. The method, therefore, has been variously modified. A number of procedures and new instruments have been tried. The most popular of these doubtless is the instrument devised by Unger. This consists

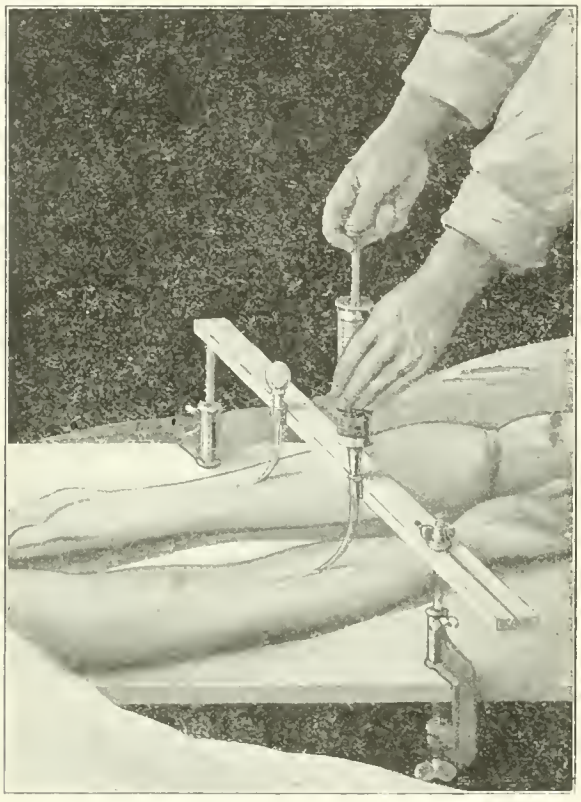

Fig. 1.—Apparatus for direct transfusion.

of a two-way cock arrangement. The blood is first drawn from the donor, the cock is then turned into its second position, and the blood is injected into the receiver. Meantime in this second position a way is left whereby an assistant washes the passage through the needle leading to the donor with salt solution, the idea being to prevent clotting. The cock is then turned back to its first position, the passageway being between the assistant and the receiver is then washed with salt solution while the operator is again drawing away another syringe of blood, preparatory to repeating the cycle. Theoretically this method requires but one syringe. If the transfusion is kept up for any length of time more than one syringe is usually required. The constant injection of salt solution is necessary in order to keep the blood from clotting in the small caliber needle, in the cock passages, and in the rubber tubing by which the needles are attached to the cock. The chances of clotting in the syringe are greatly minimized by constantly spraying the syringe with ether, but in order to keep the clotting from taking place in the needles, rubber tube, and cock passages, the injection of salt solution is constantly necessary. As to whether a man uses one or more syringes to my mind is not a very great factor, as the syringes are cheap, and if they make a clean operation it would be better to use several than to use one.

The idea in the apparatus here described is an endeavor to improve upon the instruments mentioned. The advantages which I desire to mention for this apparatus are that there are no rubber parts, the instrument being entirely of metal, that there are no joints to harbor infection or possible favorable localization for clotting. The instrument is very simple in construction, and it requires no special technical knowledge to use it. It can be operated if necessary by one man.

Description of Apparatus.—The apparatus (Fig. 1) consist of a crossbar or gallows placed upon two upright rods. The crossbar is made fast to one of these upright rods at one end, and at the other end is slotted so that it can be widened or shortened at will, thus graduating it to a table of almost any width. The two vertical rods holding the crossbars are held in two clamps respectively, one at each side so that they can be fastened firmly by hand screws to the table. The gallows is grooved in two places (as shown in Figs. 1 and 3). These grooves are made for a spring slot which closes on the neck of the needle, which I am about to describe. The crossbar can be notched on either side by the slots in several places, thus allowing several needles to be used if desired. The needles illustrated (Fig. 2) are about 6 inches long and are so curved that the point of the needle is nearly at right angles to the head. I have arranged two kinds of needles: one has a sharp point and the other has an olive tip point. The heads of the needles are made with a double collar and a neck between. The caliber of the needle is made just snug enough for the insertion of the tip of a Record syringe at its top or a metal stopper of the same diameter (Fig. 1 illustrates this feature). The needle is held firmly in the slot.

Technique.—The arms of the donor and receiver are placed under the gallows (Fig. 1), their hands being in opposite directions. The arms are made even, the gallows is screwed down to the height desired, the first needle is inserted into the recipient in the direction of the receiver's flow of blood stream (pointed away from the hand). It is then raised at right angles and the neck is pushed into the clamp on the crossbar, where it is held firm, and a metal stopper is pressed into the mouth of the needle (Fig. 1). Another needle is inserted into the vein of the donor pointing toward the hand. It is likewise raised at a right angle and pushed into the slot in the gallows, where it is held firmly. The slipping into the groove in the gallows is done very gently, and the position of the needle is not in the least disturbed. After the head is once snapped

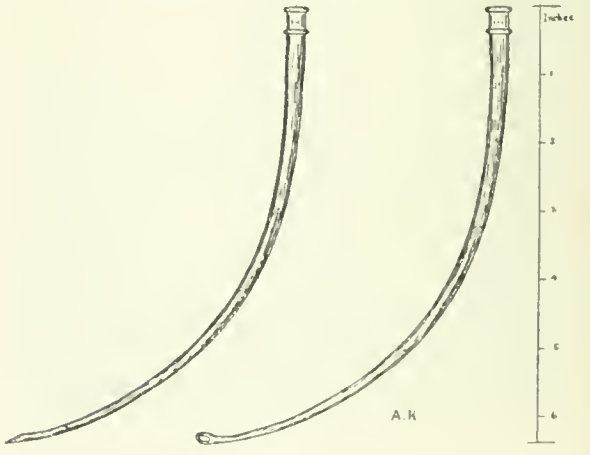

Fig. 2.—Needles used for transfusion.

into its groove the needle is perfectly steady and held firmly, flush with the upper surface of the gallows. The apparatus is now ready for the transfusion. The operator stands at the end of the table on a box or any slight elevation, so that he is above

the gallows. The syringe is inserted into the mouth of the donor's needle, and the blood is withdrawn. The operator then raises the syringe, sets the stopper, places the syringe tip into the mouth of the receiver's needle, and injects the blood into the receiver (Fig. 1). After the blood is injected the syringe is raised out of the mouth of the receiver needle and placed into the mouth of the donor needle, and the cycle is ready to be continued. The operator continues in this cycle until the quantity of blood desired has been withdrawn. The whole procedure is comfortably before him, much more so than the keys of a telephone board are before the eyes of a telephone operator. The syringe is raised and inserted from one opening to the other, and the procedure is very quick. There is no slipping of the needles out of the blood-vessels as the distances are always uniform. Where any quantity of blood is to be withdrawn, I recommend an olive

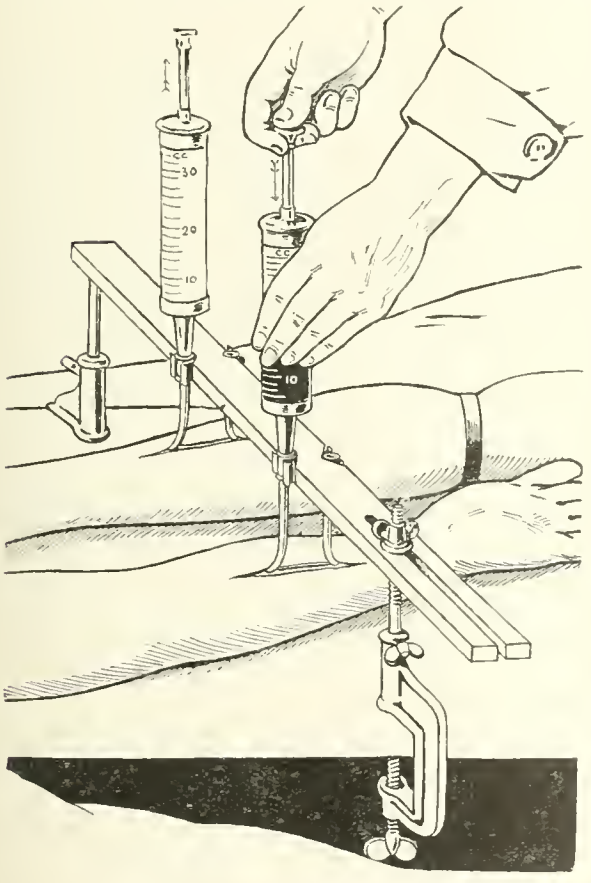

Fig. 3.—Apparatus for continuous transfusion.

tipped needle. In this case a small incision about ½ inch long is made down to the vein, a stab slit is made into the vein, the olive tip is then inserted and, if desired, can be fastened by ligature. The transfusion is then highly satisfactory and can be more easily performed.

Continuous Transfusion.—To do a continuous transfusion the procedure is as follows (Fig. 3): The vein in both donor and receiver is cut down upon by an incision about ½ inch long, the vein is exposed, and the vein is opened. Now instead of using two needles, I use four needles, one needle pointing toward the hand and the other pointing toward the heart, in both recipient and donor. The blood is then withdrawn from the distal end of the donor's vein and injected into the proximal end of the receiver's vein and withdrawn from the distal end of the recipient and injected into the proximal end of donor. The whole procedure is just as comfortably before the eyes of the operator as in the case of direct transfusion; the whole thing can be done by one man. Continuous transfusion is as yet only in an experimental stage.

Recapitulation.—There are no joints, no rubber parts. The whole instrument can be sterilized. The caliber of the needles is larger, clotting is less apt to occur. The procedure is extremely simple and can be carried out by one man.

50 East Forty-second Street.

RECURRENT ACRODERMATOSIS OF WARM COUNTRIES.

By R. RUIZ-ARNAU, M.D.

San Juan, Porto Rico.

President of the Academy of Medicine of Porto Rico.

We propose to designate by the name of *recurrent acrodermatosis*, an affection which is, by the way, quite variously interpreted, especially from the etiopathogenic point of view, and which may be observed daily in our country.

Before entering on a special study thereof, certain observations relative to the generic idea involving this as well as several other processes very common in warm countries, are indispensable.

In another work[1] we have endeavored to demonstrate that in tropical lymphangiectasies, besides the three stages of evolution noted by classical authors, to wit: (1) Infection and *inflammation* of the lymphatic vessels; (2) obstruction (or vice-versa); and (3) terminal *distention* followed by *secondary* lymphectasia it is necessary to consider one more stage: *primary* lymhphectasia, purely climatic, which, free of all infection or infestation, always preexists, and becomes later the obligatory companion of all tropical lymphangiectasic processes.

Such primary lymphectasia, which, summarily, is nothing more than a special manifestation of the permanent general state produced in the human system by the concurrence of different physical elements that integrate intertropical surroundings, comes as a substitute of that vague and undetermined notion which over a quarter of a century ago was introduced by Corre[2] under the term *lymphatexia*, provided all such matter as is to-day well known to be derived directly from tropical parasitism, is segregated from the former.

This lympectasia is responsible not only for the greater intensity and frequency of lymphangiopathic processes in our zone, but also, and principally, for their recurrent character, and constitutes a permanent state of condition of the inhabitants of warm and damp countries. It requires a certain period of time to establish itself in persons coming from other latitudes, and relief is had and the condition even disappears when the patient, whether belonging to the tropics or not, either goes or returns to extratropical regions.

In many persons, either because of perfect adaptation, or because the different accessory causes stated in the work above cited do not act upon them, such condition persists latent during life, while in numerous other cases, it becomes manifest under various aspects and different localizations by virtue of the concurrent action of those same circumstances. It then constitutes the substratum upon which very often, though not always, infection and infestation occur, giving rise, together

with their accompaniment of inflammation, obstruction, and distention of the lymph vessels, to the respective clinical manifestations of lymphangitis or filariasis.

With respect to the clinical reality of this physiopathological substratum, pure and simple, or in other words, free from infection or infestation, we would again refer the reader to the above-mentioned work, where he will also find ample explanation of the matter. It is enough to state at present that the tropical lymph stasis, pure or hygrothermic, is clinically expressed by means of various forms corresponding to as many different localizations, according to the part of the body where such lymphectasia accentuates itself sufficiently to become evident, when certain circumstances of environment provoke the lymphectasic attack. And thus, at times, it is in the radical, again, in the reticular, and lastly, in the ganglionar sections of the lymphatic apparatus of the extremities, preferably the lower, where, by recurrent outbreaks, simple lymphectasia establishes itself. The different forms ordinarily develop independent of each other, or in other words, two different localizations of the lymphectasic process are not found simultaneously in the same patient, unless as an exception.

A peculiar clinical modality, therefore, corresponds to each localization; and when the lymph stasis occurs in the radicals of the apparatus, there appear from time to time outbreaks of the dermatosis to which the present work refers.

Recurrent acrodermatosis, as frequently observed in Porto Rico, is, without doubt, the clinical expression of primary radical lymphectasia. This relation being constantly unknown, such cutaneous manifestations are often ascribed to uric acid conditions, as well as to syphilis, on account of their symmetrical or bilateral disposition in not a few cases. This error, after all, should not cause surprise, if we consider that patients call on their physician at a very advanced stage of the process of evolution of the dermatosic lesions, the real commencement of which is the varicose enlargement of the original lymphatic capillaries.

In private practice cases of tropical acrodermatosis are innumerable; but we have had occasion to study it specifically, particularly that of the feet, in the infirmaries of the Boys' and Girls' Charity Schools in Santurce, Porto Rico.

The total number of inmates of these schools varies from 400 to 500, and catalogued cases of recurrent dermatosis of the feet number 101, covering 127 attacks from 1907 to 1912 in the Boys', and from 1909 to 1912 in the Girls' infirmaries.

The number of dermatosic outbreaks occurring during the period of unstable hygrothermic conditions, that is, during the months between the two yearly seasons—the dry and cool and the hot and humid—was somewhat more than double the number of those occurring during the two seasons of settled weather conditions—87 against 40. Thus for March, April and May, the total number was 39, and the average 13; for September, October and November, the total number reached 48, and the average 16; while for December, January and February, the total was 18, and the average 6. In June, July and August, the total amounted to 22, and the average to 7. We do not intend to base a general rule on an insufficient number of observations, but believe it is useful to state the facts.

Commonly, when the patient consults his physician, there are seen at the same time: blisters full of serum or sero-pus, a great many of them broken, thus exposing the mucoid layer of Malpighi, which has been perforated in the center; softened and cracked sections of epidermis; and lastly, partly healed lesions alternating with others corresponding to the first stage, that is, papuliform pruriginous elevations, about to become vesicles.

The complaint commences by a violent itching in the regions where later the ostensible manifestations of dermatosis are to develop, specially in the interdigital spaces. This itching causes the patient to scratch, thus contributing to the congestion of the skin and to the rupture of its superficial layers, from which a small quantity of ichorous lymph issues, which, in turn, spreads the irritation and pruritus over the surrounding parts. Shortly afterwards there appear in the neighborhood of the bases of the toes, on the heel and on the side of the foot—the same not being confined exclusively to any of these places — the circumscribed characteristic lesions.

A small, hard, papuliform elevation of the size of a common pinhead or little more, quite painful under pressure, in a few hours becomes a somewhat larger vesicle whose contents, separating the epidermic layers over a certain area, transform the vesicle into a blister. Such blister soon either bursts or is ruptured by the patient, or becomes seropurulent and increases in size until it reaches that of a shirt-button. It finally bursts, disclosing a background that has a central craterlike depression, from which exudate issues for a certain time, although in some instances it dries rapidly.

In order to understand the successive linking of these lesions, we should remember that the lymphatic vessels grow on the level of each papillary layer, from a large central capillary which is joined to neighboring capillaries, thus forming a subpapillary rete. The acrodermatosic lesion begins by the varicose enlargement of these original lymphatic capillaries, which form, as is well known, culs-de-sac in the papillary layer. As a result of the excessive tension of their contents, the purely endothelial walls of the vessels pregressively distend and become thinner until they permit the serosity to reach the intercellular spaces of the mucoid layer, to break the uniting filaments of the cells of this layer; and to separate such cells until lacunar spaces are formed under the granular stratum. The granular layer is loosened in turn and becomes thinner, raising before it the stratum lucidum and the horny layers. It is easy to understand that the epidermis is separated from the papillary layer in two ways: either en masse, if adherence between the Malpighian cells is very firm, or otherwise, if it is weak, the cellular elements becoming separated from each other in order to form circumscribed spaces filled with serosity, and to constitute the vesicles and blisters from the loosening of the epidermic layers. The process is no other than that designated by dermatologists' by the name of *interstitial vesicular infiltration*, to distinguish it from parenchymatous infiltration, in which the small phlyctena is formed, on the contrary, by intracellular edema.

The total evolution of each lesion lasts from five to seven days, and the dermatosic eruption, abandoned to itself or subjected to the sole action of the numberless antiseptic or simply drying applications may be prolonged for weeks and even months; and the troublesome manifestations are very often indefinitely repro-

duced, greatly to the discomfort of the patient.

In some instances, though not often, there is observed a slight lymphangitis which, commencing at one of the lesions does not, as a rule, extend beyond the foot, nor does it become a true attack of lymphangitis of the leg, but is susceptible, nevertheless, of producing a slight fever.

Generally, the attack extends to both feet, one after the other. Sometimes it is simultaneous, obliging the patient to interrupt his daily labor because it is impossible to wear shoes or to walk. This condition may last for many weeks, unless the only efficient means of shortening its duration and of obtaining positive success with local treatment are adopted. Such means should certainly not be irritating antiseptics, as is commonly advised for the sole purpose of combating infectious germs, for although it is true that the same often intervene, they do so during the later stages of the process, and as a complication. The correct treatment consists simply in the enforcement of the dorsal decubitus maintained during such time as the acute period of the lesions may last, and until there are no further new lesions, which continue to appear for a time after the patient is confined to bed, although the latter are scarcer and less violent.

Such simple and efficient treatment having been commenced, the real action of antiseptic topical applications is produced and the involution of the eruption takes place rapidly. The exposed and softened surfaces dry quickly, pain and congestion cease, and finally the lesions heal without leaving any durable signs, the dermatosic attack being thus notably shortened, the patient being permitted to resume his daily occupations.

Dermatosis of the hands presents analogous characteristics, although different from dermatosis of the feet—apart from being less frequent — because of features derived from anatomical conditions which normally distinguish the skin of the upper and lower extremities. The lesions, in an advanced stage, acquire in dermatosis of the hands, an eczematous appearance, damp at times, but dry in many cases. However, during the first evolutive stages, it is identical with dermatosis of the feet, the period of pruriginous congestion being possibly more intensely manifest, and the papuliform elevations more noticeable; for example, it is easy to see a sort of whitish thread formed by these elevations, when they appear in series, furrowing the edges of the attacked fingers.

In dermatosis of the hands, the process extends over a greater surface than in dermatosis of the feet, where we found that it may finally adopt phlyctenular forms of greater size. As occurs in dermatosis of the feet, the affection rarely extends beyond the joints of the hand and the rest of the extremity, unless excessive fineness of the skin or other aggravating circumstances in the patient permit of its extension to the forearm.

As to the rest, dermatosis of the hands has the same recurrent tendencies, at certain times of the year, as that of the feet, and is just as rebellious under treatment. It should be noted that the same benefit may be had by confinement to bed, which, as may be presumed, is difficult to obtain, since it is not easy to convince the patient that a complaint of such nature and localization requires treatment which means to some persons a real sacrifice.

When both dermatosic eruptions coincide—which is not rare—such fact should not be really interpreted as autocontagion, but simply as two almost simultaneous manifestations of the same condition in the same subject, due to analogous general and local causes. And it is then possible to observe relief in the dermatosis of the hands very much sooner, if the patient, on account of the dermatosis of the feet, accepts the sacrifice of confinement to bed.

Apart from the general tonic-restorative treatment, principally on the basis of phosphates and strychnine, local treatment varies according to the stage of the attack.

During the prevesicular stage we have obtained excellent results by applying to the affected parts a solution of picric acid, 12 to 1000. The keratoplastic action of this agent, so efficient in cases of burns, is as efficient in the disease under consideration; to such extent that used in time it not seldom serves to abort, one might say, the dermatosic eruption. We have recently had occasion again to confirm this in the case of a North American, in whom we saw an attack of dermatosis of the hands abort in less than one week, by the sole use of the solution above mentioned.

The first stage having passed, it is then not only unfavorable, but it might possibly be prejudicial to employ this solution. We would then prefer to prescribe a salve of ichthyol, 5 grams, in sterlized vaseline, 30 grams.

Before applying the ointment we would advise that the section be washed, or even better, fomented, for a few minutes, with the following prescription:

Sodium borate.....5 grams
Boric acid.....40 grams
Boiling filtered water.....1 liter
M. Sig.: To be applied twice daily.

During the last stage we prescribe dermatol exclusively, in order to accelerate the drying of the affected surfaces.

In ambulatory treatment we recommend to the patient that he always place between the toes a little absorbent cotton, which should be frequently changed in order thus to aid in preventing irritation of the surrounding surfaces by the exudate.

Before adopting the simple local treatment above stated, we experimented with a number of applications of all kinds in the infirmaries and in private practice, without satisfactory results; on the contrary, in certain cases the state of the lesions was aggravated. We must, however, except the following salve, which appears to us to have been of some benefit in the second stage:

℞
Zinc oxide.....5 grams
Carbolic acid.....50 grams
Lanoline } āā.....15 grams
Vaseline }

Sprinkle on this a good quantity of borated talcum.

In our opinion, from the foregoing study it may be inferred that recurrent acredermatosis of warm countries, although etiologically and pathogenically analogous to other lympectasic manifestations, merely climatic, possesses sufficient anatomoclinical characteristics to entitle it to nosographic personality in the extensive field of tropical pathology.

TREATMENT OF WOUNDS.

By L. SEXTON, B.S., M.D.,
NEW ORLEANS, LA.
LECTURER ON MINOR SURGERY, TULANE UNIVERSITY.

A WOUND is a sudden solution of the continuity of the soft parts. There are fifteen adjectives describing wounds, which we will not burden the reader to remember, but many of these descriptions have a bearing on the treatment of the injury.

Immediately following this sudden solution of continuity of tissue, we have discoloration, pain, swelling, and hemorrhage.

The element of pain incident to such an injury depends largely upon the location of the wound and the character of the implement with which it was produced. For instance, a steel-jacketed bullet with high velocity may pass through the body unnoticed, the wound being discovered later by the blood trickling down from its opening. Incised wounds made by sharp instruments, as surgeons' knives, cause very much less pain than do lacerated and contused wounds. Wounds of nerve trunks, of the testicle, of the elbow, of the hands and fingers, and of the abdomen are characterized by severe pain. A wound in inflamed tissue, as produced in lancing an abscess, is always attended with great pain. Increased tension and pressure upon the sensory nerve filaments is the explanation of these painful injuries.

In all wounds there is a discharge of fibrin, lymph, and serum from the vessels which must be absorbed by some superimposed sterile gauze dressing. The arrest of hemorrhage and removal of foreign bodies is an important consideration in the first-aid treatment to injured soft parts. If an artery is severed which is too large in caliber for the bleeding to be arrested by torsion, it should be picked up, separated, and ligated. Very often if such vessels are compressed by artery forceps for a short time, they stop bleeding without other treatment. If the wound is just above some bony prominence, direct pressure will often arrest the hemorrhage better than the insertion of sutures or ligatures. Continuous oozing from the wound (as in a large amputation) may be controlled by flushing with hot sterile salt solution, or by fanning the surface briskly while exposed to the air.

A suture often acts as a ligature in arresting hemorrhage; this is particularly true if the suture is of the buttonhole variety. It should be remembered, however, that we often strangulate tissue by tying our sutures too tight in trying to arrest hemorrhage by this method. Adrenalin chloride 1 to 1000 on pledgets of cotton is a useful hemostat; it may also be injected into cavities, as the urethra, or sprayed into the nostrils to arrest bleeding. In venous oozing, elevation and direct pressure are effectual in many cases; if from an artery, the tourniquet or ligature will act better. It is embarrassing to have to open up a wound, as in the scrotum, turn out blood clots, and catch up oozing vessels at the second dressing which should have been attended to at the first.

All chemical and constitutional remedies for the arrest of hemorrhage are obsolete in wounds newly made, but are admissible in hemorrhage from the relaxed uterus and from ulcerated cancerous growths.

The next most important step in the management of wounds, after the hemorrhage has been stopped, is to cleanse them. It depends largely upon the location of the wound as to what method of cleansing should be adopted; if, for instance, it is under the clothing on a clean skin surface partly covered with hair, the adjacent tissues should be shaved to prevent the hair from infecting the wound and keeping its edges separated. If the wound is on the scalp it is best to shave the proximate skin and to lift up the edges of the flap in order to remove any foreign body which might have been forced under the scalp at the time of the accident. While this is the general procedure, it might be occasionally modified for cosmetic purposes if the wound happened to be on the scalp of a female, then under such circumstances strands of hair on either side of the wound might be tied across in order to approximate the edges.

I have had no personal experience with this method.

In lacerated or crushed injuries use hot sterile water or saline solution flushing to wash out foreign particles. A great many surgeons, however, prefer a fifty per cent. solution of peroxide of hydrogen warmed and poured into the wound. The oxidation with the blood boils out many small particles, carrying infection which might not otherwise be detected. As a matter of course, any splinters or other foreign bodies, such as iron filings, etc., should be carefully removed either with forceps or a magnet. Blood-clots and tissue with the life crushed out should be removed at the first dressing while the parts are usually benumbed, rather than wait for decomposition and sloughing before removing them. We may safely assume that most accidental wounds are infected, hence the importance of thoroughly cleaning them at this first dressing; stitches should be loosely applied and drainage in the most dependent portion of the wound provided for, as it is not good surgery to seal accidental wounds hermetically with either collodion or adhesive plaster, unless the absorption of the wound secretions is first provided for. If nerves or tendons have been severed, they should be approximated by sutures whenever it is possible to find the severed ends. If the wound is very extensive and there is likelihood of foreign bodies being driven into sensitive parts it sometimes becomes necessary to cocainize or, in the severe cases, to anesthetize the patient in order thoroughly to cleanse and approximate the parts at the first dressing.

In accidents from toy pistols, giant fire crackers, or garden rakes, or in injuries inflicted around dairies or barns and in any severe laceration and contusion of the extremities, it is considered necessary to give 2,000 units of antitetanic serum as a prophylaxis against tetanus.

In very delicate skin that has been protected by clothing in children and in females, the rough brush scrubbing act has been overdone; in fact, in the case of injuries incident to machinists, miners, railroad men, etc., with oil, grease, and iron dust or rust ground into the tissue, it is almost a physical impossibility to get rid of the foreign matter at the first dressing either by scrubbing or any other process.

A great many such cases are now dressed by saturating a pledget of cotton with spirits of turpentine or gasoline and rubbing off as much of the grease and paint as the turpentine will dissolve; then applying a ½ dilute tincture of iodine with alcohol into the wound after it has been thoroughly flushed with any of the mild antiseptic lotions.

Keeping such wounds dressed several days with a moist half per cent. carbolic solution, or 1 to 10,000 bichloride will prevent infection, and so soften up these calloused hands that what was impossible to wash off at the first dressing is easily scraped off after forty-eight to seventy-two hours' application of these moist antiseptic solutions. In all deep wounds involving large areas or injury to the bone, drainage is advisable, at least for the first twenty-four to forty-eight hours. The ordinary cigarette drain, sterilized gauze, rubber turbing, or ordinary rubber tissue may be used, according to the individual surgeon's experience. Only one certain rule should be observed, namely, the drainage must be in the most dependent portion, even if this requires a counteropening to get it. Dead spaces impossible of obliteration require drainage as do amputations of the breast and thigh and suppurative appendectomies. It should be remembered, however, that all drainage of abdominal wounds predisposes to hernia.

In wounds in the pleural cavity to evacuate pus, free drainage with double rubber tubing and, in most cases, the resection of a rib become necessary in order that the drainage may be complete. In unhygienic surroundings with untrained help to rely upon we should hesitate to close any lacerated or contused wound; under more favorable surroundings and with our individual inspection it is best to close many of them, using drainage in the cases which we would otherwise treat openly. Punctured dissecting wounds should be very rarely closed, and wounds in the palm of the hand and soles of the feet are best treated openly; those in vascular tissue where the skin is loose are perhaps better stitched with silk worm gut. It has been found best in recent wars to seal hermetically without drainage gunshot wounds produced by the steel-jacketed bullet. Whenever it is decided to close a wound, the interrupted silkworm gut suture is preferable on account of being non-irritating, less likely to infection, and absorbing no moisture. Horsehair is used with equal success in closing many external surgical wounds. Some surgeons prefer the continuous suture, others the Michel clamp, while some use the subcuticular stitch for cosmetic purposes. If the zinc oxide plaster is used to approximate wounds, small fenestræ should be cut in the plaster just above the wound to provide for the escape of the oozing or wound secretion, which always follows. The collodion dressing is applicable to superficial wounds about the face where not much oozing is expected. Wounds well sewed are half healed. Tight sutures constrict and produce necrotic tissue. One can hardly tie a suture so slack that the subsequent swelling will not tighten it; the elasticity in the horsehair suture causes it to yield when swelling takes place and it is on this account that it should be more generally used than it is. Fine silk and silkworm gut are usually preferable to the catgut where infection is feared. Any traumatic injury treated by the open method should be covered with 1-10,000 bichloride or some other antiseptic dressing. If the injury is to the leg or foot the patient had better be confined to bed to secure rest, the hand or foot placed upon a Kelly pad and kept moist by applications every three or four hours, or by the continuous hot 1 to 10,000 bichloride solution; if the wound is not infected, on sensitive portions of the skin or in children the solution should be further diluted or weak iodine mixture or boracic acid be substituted for the bichloride.

Physiological rest is important in the treatment of all wounds. Splints to the hand and immovable dressings to the joints are great time-savers in the healing of wounds. Perfect rest means less pain, reaction, and quick repair.

Whenever large raw surfaces are to be treated for a long time, it may become necessary to change to the boracic acid rather than the bichloride or carbolic. After these large raw surfaces are in proper condition, skin grafting hurries healing and prevents scar tissue. Thiersch's or any method the surgeon is accustomed to may be used; usually we inspect or remove the dressing from skin grafting too early, often lifting up the graft with the dressing. In large incised wounds it is just as essential to suture the muscles as it is the tendons and nerves. It may be difficult at times to find the proximal end of the tendon, in which case the wound should be enlarged until it can be found and mended.

Most lacerated contused wounds are better packed and left to granulate than sutured; if, however, they are sutured, a drain should first be put in, the sutures being placed far apart and loosely tied. Elevation and rest must not be overlooked in the treatment of contused wounds as they lessen pain and promote healing.

Lacerated wounds are an exaggeration of the contused wounds, only shock is greater and hemorrhage and pain less.

If an extremity is literally amputated traumatically, it is usually better to secure the blood-vessels so that there can be no more hemorrhage, treat the shock by warmth and stimulation, and leave the amputation for twenty-four or forty-eight hours until reaction has set in. If the leg or arm is hanging only by skin or tendinous attachments, where a scissors amputation will remove the limb, this should be done, but any extensive surgery had better be postponed until reaction takes place; otherwise one may get the credit of having produced a surgical death, when waiting might have saved the patient. We should always remember that hemorrhage must first be controlled before any waiting is resorted to, for hemorrhage is the most common cause of shock; however, nerve blocking with cocaine permits amputation which we otherwise would not attempt.

Punctured wounds should not be probed, if they have opened the chest or peritoneal cavity. A laparotomy should be performed and any injured viscera mended, otherwise you may have a death from shocks, sepsis, or hemorrhage, in abdominal cases.

In punctured wounds from blank cartridges, garden rakes, or barn splinters, the parts should be thoroughly cocainized or the patient given a general anesthetic, the wound opened up by a crucial incision, the foreign bodies, wads, or portion of cloth driven into the soft tissue removed, dilute tincture of iodine with alcohol dropped in, and the part packed with iodoform gauze, leaving the wound to heal by granulations from the bottom. As said before, all such cases should have the additional protection from tetanus by the injection of 2,000 units of antitetanic serum.

Gunshot wounds are usually treated without probing and by the local application of 1 to 10,000 bichloride; bullets may become encysted and do very little harm.

Prevention of infection is far more important than the removing of the bullet, which can be located by the *x*-ray and removed at any future date, provided it gives no serious trouble.

Direct penetrating wounds of the abdomen with lead bullets demand an immediate laparotomy provided a competent surgeon is available, not so much with the view of locating and removing the bullet as of mending the tear in the viscera and checking the hemorrhage. Bullet wounds in the thorax and in the extremities are usually treated expectantly without operation unless infection takes place. If a bullet passes through the chest and lodges in the spinal column, causing pressure upon the cord, immediate extraction should be performed, provided the bullet can be located by the *x*-ray.

All violently infected wounds of extremities should be put at rest at once, the patient being confined to bed; the bowels should be thoroughly opened, and large antiseptic dressings should be applied and be kept constantly moist. The less handling the better. After forty-eight hours of such continuous treatment one will often find the inflammation subsiding or a local abscess formed. Rest, in septic wounds, is more important than in any other variety of injuries.

Conclusions.—Unless wounds are suppurating very freely they are usually dressed too often.

Peroxide of hydrogen injected into cavities and sinuses often carries the infection further into uninvaded tissue. Peroxide is also too strong to apply pure to newly healed tissue.

Sterilized gauze without dusting powder is sufficient protection for any clean surgical wound.

Sterile water, saline solution, or a very mild antiseptic solution should always be given preference over the stronger antiseptics which, in destroying the pus coci, at the same time destroy the new epithelial tissue by which granulating wounds are covered.

There is no better protection against infection than the free application of large sterilized pads or dressings with which they should be abundantly covered.

Absolute physiological rest by a properly applied splint or confinement in bed is a great time saver in the healing of wounds.

Silkworm sutures are much less likely to produce stitch abscesses and should be given the preference over catgut wherever practicable.

Zinc oxide plaster has a wider field of usefulness as a surgical appliance than has been given to it.

In redressing wounds, all materials should be thoroughly softened by warm sterile water before the dressing is removed. Two thousand units antitoxin serum should be given with a local application of equal parts alcohol and tincture iodine at first dressing.

506 Medical Building.

Medicolegal Notes.

Powers of Boards of Health in Prevention of Epidemics. — The Kentucky Court of Appeals holds that the State Board of Health or a county board has authority to order that school children be vaccinated or excluded from the schools when they believe there is reasonable apprehension of an epidemic, and that the vaccination of the school children is the only means by which it can be prevented. The precise question had not previously come before the Kentucky court, but it has frequently been adjudicated by other courts, and the uniform ruling is that when there is reasonable apprehension of the outbreak of a communicable disease such as smallpox, health boards have authority to take such action. What boards of health shall do to prevent epidemics, and how it shall be done, are matters left to their sound discretion, thought they cannot adopt unreasonable or arbitrary rules or regulations, or, without cause, harass the public unless they have reasonable grounds to believe that the action is necessary to prevent or suppress the disease sought to be controlled. Courts may restrain boards of health if they undertake to exert authority not fairly within the powers conferred by statute or plainly not needed for the purpose of conserving or protecting the health of the people or preventing the outbreak or spread of infectious or contagious diseases. But the discretion lodged in boards of health in the exercise of their powers will not be interfered with unless plainly abused.—Board of Trustee v. McMurtry, 184 S. W. 390.

Malpractice—Diphtheria. — In an action to recover damages for death by diphtheria caused by malpractice, because of the failure to administer antitoxin, it appeared beyond dispute that it is not usual or customary for physicians to cause bacteriological or microscopical examinations of the contents of the throat to be made, except in cases where a membrane is present. There was no evidence to show that there was at any time any membrane present in the throat of the deceased child, and, it appearing without dispute that some cases baffle the most skillful diagnosticians, the case at bar might have been such a case, in which event the defendant could not be held liable for his failure to make a correct diagnosis and consequent failure to properly treat the patient. The law does not require impossibilities, or even the exercise of the very highest degree of skill or the utmost care, but only such reasonable care and skill as is usually possessed by physicians in the same school in the locality. There was no evidence tending to show that the exercise of ordinary care and skill by the defendant would have prevented the child's death. The medical testimony showed conclusively that the result, where antitoxin is not administered in the early stages of diphtheria, is uncertain, and that no one can say in a given case what the result would be if antitoxin were administered. It appeared without dispute that the defendant made a careful and thorough examination of the child more than 24 hours after her illness began, in which he was assisted by another physician, and that, in order to make the examination thorough and complete, the child was given an anesthetic and the cavity of the throat thoroughly explored, and that at that time there was no membrane present, and according to the evidence a microscopic or bacteriological examination was not indicated. It was further undisputed that the defendant examined the child on the evening before her death, and at that time there was no membrane present in the throat. The physicians further agreed that in the absence of a membrane or other symptoms pointing directly to the presence of the disease, antitoxin should not be administered. The other symptoms were not present in the case.—Judgment for the plaintiff was reversed, and judgment was directed for the defendant. —Hrubes v. Faber, Wisconsin Supreme Court, 157 N. W. 519.

Hernia Caused by Electric Shock.—In a railroad employee's action for hernia, alleged to have resulted from an electric shock, expert testimony that it probably resulted from a shock operating upon some weakness in the abdominal wall was admissible, without preliminary showing of such weakness; it being known and testified that such weakness necessarily predisposes to all ruptures. A witness said he saw the plaintiff hanging on the wire for two or three minutes and then, as he said, when the current was turned off, "the static stopped, and Murphy fell off into a safety." The plaintiff stated that shortly after the accident he felt severe pains in the lower part of his stomach, that grew worse, and that finally he noticed a swelling below, which increased until he went to the hospital for operation on June 9. He was injured on Jan. 25, 1913, and worked for the defendant full time, with the exception of two days, until March 17, stopping just before the strike on March 21. He said that he felt the pains in the abdomen about three weeks after the accident, and that the pain was increasing until the time of the operation. The court concludes that the jury was justified in finding that the plaintiff's hernias came from the accident, and that the finding is not against the weight of the evidence.—Murphy v. New York, N. H. & H. R. R. Co., New York Appellate Division, 157 N. Y. Supp. 962.

Examination of Physician.—The New York Appellate Division holds that, in an action for personal injuries, a physician may be asked upon cross-examination in whose interest he made an examination of the plaintiff, to show the interest or bias of the witness, although his answer discloses that an insurance company is defending the action, if not asked for the purpose of prejudicing the jury.—Di. Tomasso v. Syracuse University, 158 N. Y. Supp. 175.

MEDICAL RECORD.

New York, October 14, 1916.

HEALTH INSURANCE.

SINCE the passage of the Workman's Compensation Act it has been apparent to students of the political situation that it would be only a matter of time before the idea would be extended and there would be adopted a health insurance, or better a sickness Insurance law, not only by the State of New York but also by many of the States of the Union. The time is close at hand for such action by the Legislature of the State of New York. Whatever may be the arguments for or against such a law, we surely shall be subject to the provisions of one before many years have passed. Such being the case, it is the duty of every physician to familiarize himself with the provisions of the bill presented before the Legislature last year, or the one that is to be presented this year, and to study carefully the large amount of information that has been accumulated in the development of this particular phase of governmental paternalism. Our large medical societies have done their full duty in this respect. The Committee on Social Insurance of the American Medical Association presented to the meeting at Detroit in June a voluminous report which covers the whole subject in a thorough and very satisfactory manner; the Committee on Publication of the Medical Society of the State of New York published last February the text of the Mills bill, then before the Legislature, and commented on the special characteristics of this proposed legislation; Warren and Sydenstricker of the United States Public Health Service have published an extensive study of the subject, and the Committee on Legislation of the Medical Society of the County of New York have also considered and reported on the same problem.

The information is thus near at hand. But there is too great danger that the average practising physician will fail to do his full share in bringing about a satisfactory solution of the difficulties which surround the subject. When the Workman's Compensation Act was passed many physicians ignored it entirely, since they had little to do with the cases which were affected by it. A health insurance law, on the contrary, will affect the practice of almost every doctor in the State. His financial future will depend very largely upon the wording and construction of its clauses, and his professional development may be very seriously influenced by it. The Mills bill, which was introduced into the last Legislature, failed of passage, and a commission has been working on the subject this summer. It is not at all certain that a law will be passed this winter, but it is certain that it will advance further this year than it did a year ago.

It is therefore of the highest importance that each physician obtain the available information and, so far as possible, reach a conclusion as to what he thinks are desirable provisions for the law. He should then express those conclusions and discuss them with others, if possible, in such a manner that the Legislature may become aware of the result of the discussions. It is only by such means that a law can be framed which will deal justly with all of the parties to the transaction.

Some of the details which need especially careful consideration are the distribution of patients among physicians, the method of payment of physicians, the issuance of disability certificates, the problem of malingering, the relation to State and municipal health boards, the part to be played by the hospitals in the diagnosis and treatment of patients under the act, the extent to which benefits shall be given and the position of specialists. It is almost impossible to exaggerate the importance of such a law in relation to the medical profession.

There is scarcely a form of medical activity which the law will not touch in some way. Under the wise and intelligent administration of a carefully drawn law there is great possibility for good in improving the quality of medical treatment given to those who benefit by it and in the prevention of disease. "To enact a health insurance law simply as a relief measure without adequate preventive features would be a serious mistake, but with a comprehensive plan for disease prevention there is every reason to believe that it would prove to be a measure of extraordinary value in improving the health and efficiency of the wage-earning population." (Woodward and Warren.) It would be an excellent idea if every medical society of whatever size in this State should set aside one meeting during the coming season for the discussion of this subject. It would be a disgrace to the profession if the passage of this law should find them unprepared to present and maintain their position with their present opportunity to get themselves ready.

THE USE OF HABIT-FORMING DRUGS BY SOLDIERS.

IT has long been known in a general sort of way that drug addictions were comparatively frequent among enlisted men. Without any reflection on their capability for their duties, their potential fighting abilities, or any of the qualities necessary to make them an adequate part of a great war machine, it is usually conceded that many of the privates come from a low stratum of society, and in some cases are actually inferior constitutionally, not to say psychopathically predisposed. Men of this kind, of course, are the natural prey of drugs. They have few or no ethical considerations to restrain

them, consort freely during their leaves of absence with prostitutes and their parasites, a class which furnishes a large percentage of drug users, and chafe under the restrictions of military life to such an extent that it seems necessary for them to have recourse to drugs to help them adjust.

An exhaustive study of the use of habit-forming drugs by soldiers has been made by Capt. Edgar King, M.C., U. S. A. (*Military Surgeon*, September, 1916), whose report, unfortunately, deals with soldiers under sentence only who would naturally be expected to furnish a large percentage of drug users. He finds, as a matter of fact, 4 per cent. admittedly so and 2 per cent more suspected. He believes that among enlisted men not in this class about 1 per cent. are addicts. The majority of them acquired the habit after enlistment. King discusses briefly the well-known fact that the drug addict, in the great majority of cases, is abnormal aside from his habit, and that he takes the drug to enable him to deal adequately with the situation which would otherwise overwhelm him, or to alleviate the mental suffering caused by his failure to succeed in life. Few, if any, he found, acquired the habit through a physician's prescription, although this is the usual lay theory of its inception. The three main ways in which they became familiar with a drug was through prostitutes, through vendors, and through association with addicts, either soldiers or civilians.

It seems that in houses of ill fame the soldier is surrounded by a drug-using atmosphere, and often becomes intimate with a person who is an addict. She talks to him about the drug, saying that it "will make him fit" or "drive away the blues." In some cases she actually suggests that he use it. The second method of acquiring an addiction is through illicit vendors of the drug, who are usually to be found near a large camp. These men naturally indorse the drug in glowing terms to the soldier, suggest that he try it, and even furnish samples free to non-addicts. The third, and the most insidious, source comes from soldiers who have become addicts and spread the use of the drug among their companions. At first, this is often done innocently. The men frequently believe that the drug in question is really a panacea, and before their eyes are opened many more become contaminated. Of course, when the soldier has become a confirmed addict his moral obliquity is such that he has no hesitancy in recruiting new followers of his divinity. Then, too, it is a sort of defense reaction; he takes the drug, he must do no harm, therefore the drug is harmless, therefore he recommends it to others.

Captain King quotes a number of specific examples of soldiers who became addicts to the destruction of their efficiency. He finds that a great many of these were what he calls "potential addicts"; that is, persons who only want an introduction to the drug and fair chances of obtaining it to become addicted. These persons exist, of course, in every class of society, and it is unfortunate that in the army their opportunities of going astray are so plentiful. Perhaps the present report will effect some alteration in this state of affairs.

VINCENT'S DISEASE AND PYORRHEA ALVEOLARIS.

An apparently new malady has existed for months among the Canadian and other British troops in France, which might be described indifferently as a form of Vincent's disease with essential localization in the gums and as an acute form of pyorrhea alveolaris occurring in the young and having no necessary connection with Riggs' disease in the elderly. The two organisms which apparently cause Vincent's angina are known to be capable of exciting an ulceromembranous stomatitis, the throat being spared. On the other hand the *Entameba gingivalis*, alleged to be the cause, or a cause, of pyorrhea alveolaris, is also present as an inconstant find, in marked contrast with the spirillum and fusiform bacillus of Vincent which are constantly present and usually freely present—even in many cases in pure culture.

A preliminary report on this affection was made by Bowman in the *Proceedings of the Royal Society of Medicine*, 1916, Vol. IX, No. 4. The men applied for treatment chiefly for loosened teeth, difficulty in mastication, and in certain cases dysphagia. Vincent's angina of the usual type is regarded as extremely rare, although there is plenty of evidence to show that it is contagious. It has in fact at times been spread by common eating utensils, as secondary syphilis may be, and even by inoculation (biting). In the classical descriptions of Vincent's angina we find sufficient mention of the progression of the disease from the fauces to the gums, which may show either the ulcerating or membranous form of the disease. That this affection may begin in the gums, with or without extension to the throat, is, however, not yet admitted. In the present epidemic the process appears to be localized to the gums—hence the ready confusion with pyorrhea.

The patients who present themselves for treatment of the stomatitis complain much of depression and prostration. Fetor of the breath may even precede the local manifestations and is marked throughout. The gums bleed readily, are injected, retracted, and spongy. Pus may be squeezed from the gum margins. The teeth may be loose or simply tender and unequal to chewing.

Despite the fact that the *Entameba gingivalis* appears to play but a secondary rôle, if any, in the genesis of this affection, a solution containing ipecac gives the best results, whether introduced into the pus pockets beside the teeth or applied to ulcers in outlying zones. But cures are never obtained until Vincent's organisms have disappeared from the mouth. This is best effected by an injection of salvarsan which is a spirillicide. On account of its possible twofold etiology, a mixture of ipecac and arsenic is recommended in chronic cases. This same mixture is of great value in typical Vincent's angina when chronic. A mixture of Fowler's solution and wine of ipecac is kept in stock, as the epidemic of gingivitis shows no sign of subsidence. It would thus appear that the Vincent organisms, if they are not actually a cause of pyorrhea alveolaris, are at least powerful synergists to the entameba in this relationship.

ERYTHEMA MULTIFORME LEADING TO DEATH BY UREMIA.

Clinicians are familiar with a form of symptomatic erythema multiforme due to severe visceral lesions. It is probable that the fatal ending in some of these cases is due to the progress of the underlying disease, in which the cutaneous lesions play a sort of terminal rôle, as in certain cases of septicemia. Quite different is the status when an individual who seems perfectly sound develops first erythema multiforme and then nephritis.

In *La Riforma Medica* for July 10 Arullani reports a case which may be interpreted at the pleasure of the reader. A peasant woman of 30 entered the clinic apparently healthy, save for the existence of a dermatosis of three years' duration. It was seated chiefly on the face and dorsal aspects of the hands and forearms, and was not at all like an eczema or other familiar dermatosis. It was quite free from itching or scratch marks. Aside from the attributes of an erythema, it presented an infiltration to the touch and at times vesiculation. Despite its chronic character the author regarded the condition as an exudative erythema, but he evidently reserved the privilege of changing the diagnosis to eczema, and indeed the latter would doubtless have been the diagnosis of the ordinary dermatologist, despite the absence of itching and scratch effects. In fact, he speaks of its eczematoid character. It appears to have yielded readily to a tarry ointment. The eruption returned, however, soon afterwards without apparent cause in the form of vesicles which itched intensely, the entire process resembling an ordinary eczema. At the same time the general condition was seen to be involved. There was fever and albumin appeared in the urine. Side by side with evidences of nephritis vesicles continued to appear and disappear under desquamation. In a few days oliguria, edema, and uremic phenomena were in evidence and in the course of a fortnight death took place. The disease had resisted all treatment from the start.

In summing up the author concludes that the skin lesion was originally an erythema exudativum commune, evidently multiform to some extent. Its occurrence in a healthy woman is understood to mean that in some way it led to a fatal nephritis. The most plausible view is that it was due to local infection and that the germ or its toxic products were able to set up nephritis in connection with elimination. It is by no means necessary that the local focus be a suppurative one, for pyogenic cocci do not invariably cause suppurative lesions and nephritis due to local infection is not usually a suppurative process.

Luetin in the Diagnosis of Syphilis.

In certain regions where diseases prevail which can give a Wassermann positive in the absence of syphilis the diagnostician naturally turns to luetin to check up the former. Thus in certain countries are found side by side malaria, leprosy, and kala-azar, each of which may have to be excluded in making a diagnosis of syphilis because they too may give a positive Wassermann. A year ago in the Milan Serotherapeutic Institute and Marine Hospital at Taranto Dr. G. G. Conte (*Annali di medicina navale e coloniale*, March-April, 1916), began a comparative study of the two diagnostic reactions, luetin and the Wassermann, the former, as is known, being specific and intradermic. In primary syphilis, 7 cases, the luetin reaction was negative throughout, while in 2 cases the Wassermann was positive. In a second series of more advanced cases all the Wassermann tests were positive and two reacted to luetin. Summing up, the Wassermann was positive more than twice as often as the luetin test. In testing secondary syphilis, in 20 cases, the luetin positives slightly surpassed the Wassermann in frequency; while in six tertiary cases the luetin predominated notably over the Wassermann. These figures speak for themselves, but the material is of course small for generalization. In tardy and tertiary syphilis, especially in involvement of the nervous system, luetin may make the diagnosis after the Wassermann has failed. At the same time in general paralysis the Wassermann often gives 100 per cent. positive. Kafka in 1915 found luetin positive in 100 per cent. of tabetics and 90 per cent. of cerebral syphilitics, while in general paralysis it was positive in but 50 per cent. On account of the trustworthiness of the Wassermann reaction in metasyphilis it is perhaps best to reserve the use of luetin for cases in which the Wassermann is negative. It appears that luetin, however sensitive the reaction, has a slower response than the Wassermann, so that after failure it may be repeated. In very early syphilis, luetin is not likely to succeed when the Wassermann fails, reversing the rule in tertiary syphilis. A luetin reaction may be early or late, may vary much in degree; especially may it be delayed in tertiary syphilis; but, however it occurs, it should be regarded as pathognomonic when positive, although Conte prefers not to call it absolutely pathognomonic.

Trench Fever, Pappataci, and Dengue.

When Prof. C. Martelli of Rome first read of trench fever in a British periodical, he inferred that this affection was nothing more than "three-day fever," which in turn he held to be an abortive or anomalous form of pappataci or of barrack fever. Since this inference he has looked into the subject and finds his original views strongly confirmed. In *Il Policlinico* for July 9, however, Filippini takes some exceptions to Martelli's views. It is admitted that trench fever and three-day fever have much in common (headache, vertigo, pains in the bones and muscles), but such symptoms are found in all acute infections. A study of the fever curves, however, shows dissimilarity, three-day fever usually terminating in perspiration at the end of seventy hours—exceptionally at the end of two or four days. Trench fever, on the other hand, lasts seven or eight days, though often with an intermission at the third day. There is, indeed, a variation in which defervescence comes on the third day, but in which frequent periodical relapses occur, so that we have practically a recurrent, not a three-day fever. In both fevers we note the presence of the same blood changes—lymphocytosis, basophilia. In regard to etiology, there are differences. Three-day fever is evidently due to a virus, a filtrable virus, of which the ultramicroscope gives no information. In trench fever there is some evidence that the virus is associated with the corpuscular portion of the

blood. Filippini associates trench fever with the so-called seven-day fever known in India, which resembles closely the more familiar type of the former, in that it may show during this period a remission. Now this seven-day fever is identified by Castellain and Chalmers as a variety of dengue. The author does not subscribe to this conclusion, however, any more than to that of Martelli.

News of the Week.

Paralysis Decreasing.—The epidemic of poliomyelitis in New York has decreased steadily since the first of October. For the week ending October 8, there were reported only 90 cases, giving a daily average of 15. On that date there were in the hospitals 1,537 patients suffering with the disease. In the other parts of the State and in New Jersey also the same decrease was noted. Federal inspection of interstate travel to and from New York, which was begun last July, was discontinued on October 3, under instructions from Surgeon General Blues of the U. S. Public Health Service.

Red Cross Supplies to Europe.—A motor ambulance, the gift of the Sons of St. George of Wilkesbarre, Penn., was shipped from New York to Serbia recently through the Red Cross, which forwarded also hospital garments and surgical dressings. Two large motor trucks are also on the way to the Belgian Red Cross, and a large ambulance for the French Red Cross is now in New York awaiting shipment. This ambulance is the gift of the Chicago Chapter, which has also recently forwarded a carload of surgical dressings to the American Fund for French Wounded, Paris.

Prize for Artificial Hand.—Through the Société Nationale de Chirurgie of Paris, an anonymous donor has offered a prize of 50,000 francs for a mechanical apparatus best supplying the place of the hand. Competitors must belong to the allied or to neutral nations. They are to present to the society crippled men who have been using the apparatus for at least six months. The society will also experiment with the apparatus on cripples for as long a time as is thought necessary. The apparatus to which the prize is awarded is to remain the property of the inventor. The competition will be closed two years after the end of the war. Competitors are requested to send their apparatus and a description to M. le Secrétaire Général, So-Société nationale de chirurgie, 12 rue de Seine, Paris.

Personals.—Dr. Chevalier Jackson of Pittsburgh, Pa., has been appointed professor of bronchoscopy and esophagoscopy and direct laryngoscopy at the New York Postgraduate Medical School and Hospital and will assume his official duties in November.

Dr. Isaac Levin of New York has resigned as associate in cancer research in the George Cricker Special Research Fund, Columbia Univeristy, to accept an appointment as clinical professor of cancer research in the University and Bellevue Hospital Medical College.

Dr. A. I. Ringer, formerly assistant professor of physiological chemistry at the University of Pennsylvania, has been appointed professor of clinical medicine (diseases of metabolism) at the Fordham University School of Medicine, New York.

Dr. James R. Hayden of New York has resigned the chair of genitourinary diseases in the College of Physicians and Surgeons, Columbia University.

Dr. Timothy Matlack Cheesman, because of ill health, has resigned as a member of the Trustees of Columbia University, an office which he had held since 1904.

Christian Science Sanatorium.—In accordance with the wishes of Mrs. Eddy, who in 1909 proposed that the Christian Scientists should "establish and maintain a Christian Science resort for the so-called sick," the directors of the church have recently accepted a gift of twenty acres of land in Brookline, Mass., and on this will erect buildings as may be necessary. The plan is to have Christian Science treatment given under ideal conditions, and to give as well such instructions in practical methods of caring for those under treatment as may be consistent with Christian Science teachings.

"Healer" Wins Point.—After a four years' fight W. V. Cole of New York, a Christian Science practitioner who was convicted of the illegal practice of medicine, has been granted a new trial by the Court of Appeals. In substance, the court decided that the exception contained in the medical license law, to the effect that its provisions should not prevent the practice of the religious tenets of any church was broad enough to include the methods used by the followers of Christian Science, and, therefore, exempted them from the requirement of passing medical examinations and being admitted to practice as physicians.

New Orleans Death Rate.—The Health Commissioner of New Orleans announces that during the month of September the death rate in the city fell to 13.79 per 1,000, the lowest rate recorded, it is said, in one hundred years.

Ice Cream Starts Epidemic.—An epidemic of typhoid fever is reported in Harrisburg, Pa., 400 cases having occurred in the city and its vicinity. It is thought that ice cream made from contaminated milk has been the main factor in the spread of the disease.

Gifts to Charities.—The will of George H. Schrader of Brooklyn, by which the bulk of his estate, estimated at $2,000,000, is bequeathed to the Caroline Rest, Hartsdale, N. Y., was admitted to probate in Westchester County on October 3. Mr. Schrader was lost at sea while returning to the United States from Iceland, and the probate of his will has been delayed until proof of his death could be obtained.

The Nurse Endorsed.—A recent issue of *School Health News*, a publication of the New York City Department of Education, contains the following extract from an examination paper: *"Question.* Tell why the children and parents should respect the school nurse and follow her advice. *Answer.* Whatever our nurse tells us we should bring the news home and the mother should not say the nurse is crazy, because she is not crazy. She would not have the position if she was in that state."

Unusual Suit.—A physician of New York City has recently filed in the Supreme Court a suit against the New York Telephone Company for $10,000, alleging that because of the failure of the company to list his office telephone in one of the 1915 directories, he suffered damage to this amount.

Gifts to Medical College.—At a meeting of the trustees of Columbia University, New York, on October 2, the following gifts to the College of Physicians and Surgeons were acknowledged: For the fund for surgical research, $5000 from Mr. Clarence H. Mackay; for salaries in the department of pharmacology, $1385 from an anonymous donor; for the medical school removal and rebuild-

ing fund, $1000 from Mr. W. V. King; for salaries in the department of physiology, $1000 from Prof. and Mrs. F. S. Lee. It was also announced that about $7000 had been received for the proposed new building for the recently established dental school connected with the college.

Cornell University Medical College entered its nineteenth session September 27, 1916, with a total of 131 students. An address was made by Dr. Frank Sherman Meara, professor of therapeutics, and the students were also welcomed by the dean of the college, Dr. William Mecklenburg Polk. The enrollment is as follows: For the degree of M.D., first year, 37 (not including students entering the Ithaca division for the first year); second year, 37; third year, 26; fourth year, 25; graduate students, not candidates for the degree, 4; candidates for the degree of Ph.D., 2; making a total of 131.

Harvey Society.—The first of the twelfth course of Harvey Society Lectures will be given on Saturday evening, October 14, at 8.30, in the New York Academy of Medicine, by Prof. J. S. Haldane, of the University of Oxford; title, "The New Physiology."

New York and New England Association of Railway Surgeons.—The twenty-sixth annual session of this association will be held at the Hotel McAlpin, New York, on Wednesday and Thursday, October 18 and 19, under the presidency of Dr. D. H. Lake of Kingston, Pa. Details as to the program, etc., may be obtained from the secretary, Dr. George Chaffee, Little Meadows, Pa.

The Late Dr. Judson.—At a recent meeting of the Council of the New York Academy of Medicine the following minute was adopted:

"Dr. Adoniram Brown Judson, who died on September 20, 1916, was born in Maulmain, Burmah (where his father was stationed as a missionary), on April 7, 1837, graduating from Brown University in 1859. He then attended lectures at Jefferson Medical College. The Civil War breaking out before he had completed his course, he entered the navy as assistant surgeon in 1861, was promoted to passed assistant surgeon in 1864, and to be surgeon in 1866, resigning in 1868. He was given the degree of M.D., 1865, by Jefferson Medical College, and in 1868 a similar degree *ad eundem* by Bellevue Hospital Medical College. After several years spent in work connected with the Health Department of New York City, Dr. Judson devoted himself to orthopedic surgery, and in 1887 assisted in forming the American Orthopedic Association, of which he was vice-president in 1889, and president in 1890. For thirty years he was orthopedic surgeon to the Out-Patient Department of the New York Hospital, resigning in 1908.

"Dr. Judson was a man of lovable personality, prone to see that which was good in every man, and overlooking his failings. He was glad to extend a helping hand to the younger men in his specialty, and if he differed from his confreres on any topic did so in a way that did not give offense. Whatever Dr. Judson started to do he did it with his whole heart and he did it thoroughly. In nothing was this more clearly shown than in his connection with the New York Academy of Medicine. From 1886 until the time of his death Dr. Judson was our statistical secretary, and to his diligence and painstaking accuracy we owe the exact record which we possess of the part which every fellow of the Academy has taken in its activities. While chairman of the Section of Orthopedic Surgery, he had full records made of the transactions of the Section, and saw to it that these were published in full in many journals both in this country and abroad, as well as being filed on the shelves of our own library, and in this and many other ways he made this section one of the most widely known throughout the medical world.

"In his death the New York Academy of Medicine has lost one of its most faithful and conscientious officers, and in acknowledgment of his services the Council of the Academy desire this record of their appreciation to be spread upon the minutes and a copy sent to his family and to the medical press."

Obituary Notes.—Dr. GEORGE B. WILSON, medical director and commandant of the United States Naval Hospital at Chelsea, Mass., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1889, a captain in the United States Navy, and a member of the American Medical Association, the Massachusetts Medical Society, and the Norfolk District Medical Society, died on Oct. 1, from blood poisoning, after a brief illness, aged 53 years.

Dr. BERNARD C. GUDDEN of Oshkosh, Wis., a graduate of Rush Medical College, Chicago, in 1879, and a member of the American Medical Association, the State Medical Society of Wisconsin, and the Winnebago County Medical Society, died suddenly at his home on September 15, aged 59 years.

Dr. HERBERT MARSHALL HOWE, formerly of Philadelphia, a graduate of the Medical Department of the University of Pennsylvania, in 1865, died suddenly at his summer home, Ferry Cliff, R. I., from heart disease, on Oct. 1, aged 72 years.

Dr. DAVID MAGIE of Princeton, N. J., a graduate of the College of Physicians and Surgeons, Columbia University, New York, in 1863, and a member of the Medical Society of the State of New York, the Medical Society of New Jersey, the Mercer County Medical Society, and the Association of the Alumni of the College of Physicians and Surgeons, died at his home on October 3, aged 75 years.

Dr. JOSIAH HORNBLOWER of Jersey City, N. J., a graduate of the New York University Medical College, New York, in 1860, and a former member of the New Jersey State Legislature and of the Jersey City Board of Education, died at his home on October 5, aged 80 years.

Obituary.

PROFESSOR VINCENZ CZERNY,

HEIDELBERG.

WITH the death on October 3, at the age of 74 years, of Excellenz Wirklicher Geheimrat Dr. Vincenz Czerny, professor of surgery at the University of Heidelberg and director of the Institut für experimentelle Krebsforschung, there passed one of the most notable figures of that great center of medical practice. He was born in 1842 and was educated at the Universities of Prague and Vienna, receiving the degree of M.D. from the latter in 1866. His work in surgery began under Billroth in Vienna; in 1871 he was called to Freiberg, and in 1877 went to Heidelberg, where he remained until his death, in spite of an invitation in 1894 to return to Vienna to take the chair left vacant by Billroth.

Czerny was one of the few big figures of what has been called the Billroth school, that coterie of German surgeons, composed of Billroth and his

pupils, which was really the advance guard of modern surgery. Until their advent, the French school of surgeons, and even Langenbeck in Germany, had dealt principally with surgery of the extremities, and Billroth was practically the first to undertake surgery of the viscera, the technique of which he and his assistants developed. Among this group Czerny himself was most remarkable for the broad interest which he took in surgery; his scientific work embraced practically all its general and special fields as we have them to-day, covering operations on the larynx and esophagus, resections of the stomach and intestine, gall-bladder surgery, hernia operations, and the whole domain of gynecology. The impression he gave was that of a general practitioner treating his patients by surgical methods; his interest in the welfare of his patients, his anxiety for the well-being of his fellow men, contrasted strikingly with the purely technical viewpoint of the great majority of German surgeons. His desire to alleviate suffering was, indeed, the main reason for his early interest in cancer research. He had seen, he said, during a single year nearly 400 cases of cancer, and he felt that, while the surgical treatment of the disease was constantly improving (he himself had contributed largely to its progress), the ultimate results were discouraging and other means of treatment must be found. To this intense longing for ability to relieve the numerous sufferers who passed through his wards may be ascribed, also, his enthusiastic reception of new methods of treatment as they were suggested. It was a wonderful proof of the energy, versatility, genius, and devotion of the man that at the age of sixty-five, a time when most men feel ready to lay down their burdens, he undertook, in the face of much opposition and many difficulties, the establishment of an institution for the treatment of cancer and research into its cause, carried it through to a successful conclusion, and in 1906 had the satisfaction of opening the Heidelberg Samariterhaus. From that time until the day of his death his time and thought were always at the service of that institution.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE NATIONAL UNION—COMMISSION BEFORE PARLIAMENT—CHEAP DRUGS—STATE GRANT FOR MEDICAL BENEFIT—CHOICE OF DOCTOR—PANELS—DR. HAMILTON.

LONDON, Sept. 9, 1916.

THE National Medical Union has brought before the Commission now sitting at the House of Commons the working of the Health Insurance Acts, urging the repeal of the medical benefit section on the ground that the panel system must be regarded as an admitted failure. This view will hardly be generally accepted, but in support of it the following defects, among others, are laid down: (*a*) Pressure by committees leading to the prescribing of cheap drugs and stock mixtures, with, in addition, what amounts to a pecuniary bribe (the "floating sixpence"). In this way the attempt to keep down the drug bill is sometimes obviously made. (*b*) Perfunctory attention is alleged to be the result of excess of work, seen in congested waiting rooms, and want of time for adequate examination of patients. (*c*) Division of the profession, due to one section of it being established as a state monopoly at the expense of the other. (*d*) The state grant for medical benefit has actually in some cases been extended to unregistered persons and to various quacks.

Further dissatisfaction is felt by insured persons who prefer to choose their own doctor, and as they have to pay the panel doctor as well they feel they are paying twice over. The occupation fees of these persons go to the panel doctors, who are therefore said to have an interest in transferring their liabilities to others, particularly to poor-law, hospital and public institutions.

The profession objects to interference from the outside and the attempts to control medical certification in the working of the Insurance Acts has led to a good deal of friction—in Ireland it amounted to a deadlock at one time. The free choice of a doctor has always been admitted as theoretically a necessity, and Mr. Lloyd George held this as important until the Insurance Commission limited it to men on the panel. Permission to make "own arrangements" was refused by many insurance committees. This brought about a surplus in the medical benefit fund from the contributions levied on insured persons who refused to select a panel doctor. Those sums were distributed among panel doctors but counsel's opinion pronounced such distribution to be illegal, and even declared it to partake of "the nature of a dodge."

Insufficient sanatorium accommodation leads to unsatisfactory results. We have only 300 beds for tuberculous insured persons in the County of London; there is no provision under the Acts for consultations, operations or special treatment or diagnosis. Under the compulsion through the state there has been a wholesale transfer of private patients to the panels—an unsatisfactory consequence to the great majority of the profession. Insurance has not been restricted to those properly entitled to it. The Medical Union is not opposed to National Health Insurance for the necessitous classes, but the Commission of the Faculty indicates grounds on which exception is taken to parts of the existing scheme and administration of the benefit section of the National Health Insurance Acts.

A Knighthood of the Order of St. John of Jerusalem has been conferred on Dr. Hamilton for services rendered during the war. He is a B.A., M.D. (Dublin) and D.P.H. (London). He is author of "The Flora and Fauna of Monmouthshire," and has been in practice in Monmouth for many years.

OUR LETTER FROM ALASKA.

(From Our Special Correspondent.)

POLAR ICE-PACK AND OCEAN CURRENTS AS A MEANS OF SPREAD OF DISEASE.

ST. MICHAEL, ALASKA, Aug. 25, 1916.

IN the year 1912, when the Swiss savant, De Quervain, started to cross the great inland ice-cap of Greenland from the west coast to the eastern shore, in latitude about 70° North, he found the Danish authorities in Jacobshavn were fully awake to the dangers of infection, and he obtained permission to cross this gigantic glacier, which covers the whole of Greenland with an ice barrier almost impassable, only by giving a solemn undertaking that he would kill all the dogs in his expedition before leaving the glacier to enter the village of Augmagsalik, on the east coast.

This precaution was deemed necessary by the Danes because it was feared that the expedition

might be the means of spreading to the villages of the east coast of the island a disease which was prevalent along the western shore, and which had infected nearly all the dogs of the villages in that vicinity. Thus it will be seen that the Danish government, whose methods of caring for the Eskimo inhabitants of its Arctic possessions might be studied with profit, was working to prevent the spread of diseases among the domestic animals of Greenland as well as among the people who inhabit Danish America.

It has occurred to me, after listening to certain discourses by a man who has had many years of experience in the North, on the subject of polar ocean currents, that these currents may possibly be a means of spreading diseases from the Alaskan natives to those of the east coast of Greenland.

It has been pretty well demonstrated, and it is agreed by all who have studied the matter, that the currents from Bering Strait flow across the Polar area into the North Atlantic Ocean. This was proven conclusively by the drift of the Melville-Bryant casks, which were placed on the ice of the Polar pack north of Bering Strait. Several years later a number of them were picked up floating in the North Atlantic. The only difference of opinion on this subject for a number of years has been the particular course taken by these casks in their long journey across the Polar Sea, though the voyage of the Karluk in 1913 has about settled that matter to the satisfaction of all interested.

From my own observations, and from discussing the matter with others who have had even better opportunities than I for observation, I have concluded, as has already been written in these pages, that a large percentage of the native inhabitants of Alaska are suffering with communicable diseases. Tuberculosis especially is very prevalent, and the almost entire lack of sanitary measures, which prevails in Alaska, permits it to spread unchecked. This absence of proper sanitary precautions may be endangering the life of other tribes of dwellers in the far North, as will be seen by a further perusal of this letter.

The natives of the villages of Alaska, as well as the white residents, are in the habit of placing refuse matter, garbage, etc., upon the sea ice in front of their habitations during the long winter and spring months. This ice, carrying tons of garbage and refuse matter from Alaska, floats away to the northward with the breaking away of the ice from the shore in early summer, to become incorporated into the great ice-pack which covers the whole of the Polar area. Thus the disease-laden ice-floes from Alaska, carried by the ocean currents, after a journey of thousands of miles, come grinding along the east coast of Greenland on their way into the North Atlantic. This process has been going on through the ages, and it is the deposit of the solid matter brought across the Polar Ocean by the ice, which has formed the Grand Banks of New Foundland at the point where this stream of ice meets the warm waters of the Gulf Stream.

Is it not likely that these huge rafts of ice, as they come crowding down against the rocky coast of Greenland in the final stages of their long journey across the Arctic seas, may deposit some of their germ-laden filth, from the Alaska villages, on that shore, and thus spread the diseases from our own territory to the practically isolated people of East Greenland? Of course, this ice-pack, drifting south into the North Atlantic, appears to one who sees it to be pure white. It has been covered with snow, which obscured the vast piles of dirt which were visible at the beginning of the journey, so that while this ice appears to be about the purest thing in the whole world, it may conceal unseen dangers, even greater than the evident dangers to navigation, which are so well known and recognized by everyone.

A traveler who has visited many of the native villages on the west coast of Greenland, as well as most of those on the Alaskan shore, told me that to a casual observer it would appear that there is much more tuberculosis among the natives of Alaska than among those of the west coast of Greenland. He stated that while he had never visited the east coast of Greenland, he had heard that the people there are much more subject to tuberculosis than those on the western side of the island, thereby more nearly resembling the Alaskan natives. This, too, in spite of the fact that they are much more isolated, coming but rarely in contact with the civilized world. The reason for this lack of communication with the outside world is the flow of the ice streams down that shore, making navigation very difficult.

It is probable that this journey of refuse matter on the ice from Alaska to Greenland requires a period of from five to seven years, and one might suppose that the hard freezing to which any organisms would necessarily be subjected through successive years, might destroy their viability or virulence so that there would be no danger of infection. It is the opinion of the writer, however, that in view of the high resistance of the bacillus of tuberculosis, of anthrax, of typhoid fever, and of other infections, such organisms incorporated into the ice off the shores of Alaska could follow the ice flowing north through Bering Sea and Strait, the Arctic Ocean, across the Polar area, and thence into the North Atlantic Ocean with their virulence but little or not at all attenuated.

It would be interesting to get an expression of opinion from some the Danish scientists who have studied these matters, as well as some actual statistics regarding the prevalence of tuberculosis and other diseases on the east coast of Greenland as compared with the west coast natives. If it is found on investigtaing this matter that Alaska is a possible source of infection to the natives of this barren Greenland shore, it would be the duty of the United States to take steps toward the prevention of the spread of diseases in this manner.

Not only the natives of the Greenland shore would be endangered by this means, but the health of the inhabitants of Iceland and even Labrador and New Foundland is to be considered; and when it is realized that some of these organisms may not sink to the bottom when the ice melts away, but remain in suspension and be carried with the current of the Gulf Stream to the Scandinavian shore, the matter might have a more far-reaching result than above outlined.

It must be remembered that the last of the Melville-Bryant casks found was one picked up on the shore of a small island just west of Tromso, Norway. It was, in all probability, carried by the ice-pack into the North Atlantic until it was freed upon the melting of the ice on the New Foundland Banks, and then floated with the Gulf Stream to the Norwegian coast.

This theory of the spread of diseases from Alaska to Greenland may appear unusual, but it is at least worthy of thought, and much good might result from a thorough investigation of the matter. In

fact, as Labrador and New Foundland (a Crown Colony of England) as well as the Danish Colonies in America and even the Mainland of Europe, are possibly affected by the carrying of refuse matter from Alaska by ice-floes, the services of an International Commission of scientists from all the countries concerned might do much toward the prevention of the spread of diseases in the lands bordering on the North Atlantic Ocean.

8. Hospitals and Workmen's Insurance. F. J. Cotton.

1. The Importance of Early Reduction of Fractures with Displacement.—William Darrach holds that fractures should be considered in the same emergency class with ruptured ulcer and acute appendicitis, and that hospitals should be so equipped that the *x*-ray plant is available at any hour of the day or night, including Sundays and holidays. He believes that a more exact replacement can be accomplished in the first few hours than if the reduction be delayed, especially if that delay be a matter of days. The percentage of perfect anatomical results will be much higher with early reduction. The ease of reduction to a large extent will vary inversely with the time elapsed since the injury. The additional trauma caused by manipulations during reduction will be reduced. The evil effects of pressure of a displaced fragment on adjacent structures will depend on the duration as well as the amount of that pressure. With a more perfect reduction comes a decrease in the amount of new tissue necessary to repair the injury, which means a lessening of the period of disability and a more complete return of function. Lastly, the amount of pain and discomfort subsequent to the reduction will be lessened.

2. The Treatment of Hip Fractures.—F. J. Cotton says that it is obvious that there are two classes of hip fractures—the trochanteric and the subcapital. There is no question of union in the trochanteric cases; they unite by massive callus, usually promptly. The question is purely one of deformity. There is apt to be an outward rotation easily taken care of, but the real deformity is a coxavara type. With this goes a tendency to adduction contracture, muscle shortening, common to all hip injuries. Any treatment that insures an adequate amount of abduction is suitable for this class. The subcapital breaks, on the other hand, are essentially intracapsular, and therefore have no massive callus. Some are impacted in the beginning, and if they stay impacted they unite by bone slowly. If they start loose or work loose they do not unite by bone and produce cripples. It has been the author's idea to secure to the loose fractures the advantages of impaction; to reimpact those that needed correction, and to fix them all in moderate abduction. This he has done in some thirty cases during the past six years. The method has been of hammer impaction, after reduction, and the application of a plaster spica. His results he considers encouraging since no one has shown any better ones in intracapsular cases.

3. Certain Facts Concerning the Operative Treatment of Fractures of the Patella.—Charles L. Scudder and Richard H. Miller describe the operative treatment of fractures of the patella which has been employed at the Massachusetts General Hospital. This method has consisted in approaching the joint through an ample incision, removing gently all obtainable blood-clot, freshing the bony surfaces of the fracture, approximating the fragments by manual pressure, suturing the capsule and torn fascia with chromic catgut, closing the skin wound, immobilizing the knee for a few weeks, allowing the patient to walk with the knee still immobilized, and using active motion and massage early after operation. This method was studied to see whether it was satisfactory or not and how it could be improved. In a study of twenty-two cases two facts stand out prominently. First, 81 per cent. of the cases have demonstrated bony union of the patella following the use of the absorbable suture combined with digital and suture approximation. This means that there were 19 per cent. of failures in securing bony union and that the fracture was not reduced in 19 per cent. of the cases. The functional disability most evident in this series was a very considerable limitation of flexion of the knee, 39.5 per cent. of the cases having less than full flexion. It would seem from this series that in order to improve the results of the operative treatment of patellar fractures more care must be taken to secure bony union through accurate reduction of the fragments of broken bone and that a more accurate and secure suture must be used to maintain reduction. An encircling suture of kangaroo tendon is most satisfactory. In such cases as need more than manual reduction of the fragments the patellar clamp devised by Dr. Scudder may be employed with gratifying results.

5. The Flexed Spica and Wheeled Chair in the Treatment of Fracture of the Neck of the Femur.—G. A. Moore describes a flexed spica which is a modification of Whitman's method of treatment of hip fractures. Reduction of deformity and apposition of the fragments is maintained by essentially the same means. The chief difference is that instead of the abducted and extended position of the leg it is immobilized in the abducted and flexed position, permitting the patient to assume the sitting posture. Seventeen patients have been treated in this way, fifteen being over fifty years of age and nine over seventy years. The results have shown that maintenance of the leg and body in the same horizontal plane are not essential to union or good functional results This method was devised for old, feeble patients who are able to tolerate some appliance for immobilization, but in whom methods necessitating recumbency seem inadvisable. With the exception of one old lady, upon whom a double cast was applied, all have been in chairs daily throughout convalescence. Strength and general nutrition are maintained by the exercise of pushing themselves about in a wheel-chair, so that when the cast has been removed these patients have been able to use crutches at once.

2. Extensive Subdural Hemorrhage After Trauma.—Charles A. Elsberg reports the case of a man who, after an automobile accident, was unconscious for several hours and then seemed to have suffered little for a

period of nearly two months. The only change observed was in his mental condition, which seemed to have been somewhat altered. He was more talkative and laughed immoderately without cause. He then slipped in getting out of the bath tub and gave his head another hard knock, after which he was unconscious for forty-five minutes. As a result of examination at this time the diagnosis of extensive hemorrhage or abscess was considered probable and the patient was sent to the hospital. The mental condition of the patient was puzzling. He was at first extremely noisy, talkative, and made an effort to be funny. After a few days he became drowsy and the left upper extremity became completely paralyzed, not spastic; the left half of the face was involved, and the lower extremity was paretic. The sensory disturbances were marked in the upper extremity but less so in the lower. As the symptoms increased in severity and the right optic nerve showed numerous small hemorrhages, an exploratory operation was decided upon. A button of bone was removed from the front of the middle of the right motor area and the dura was incised. A large quantity of dark colored fluid escaped. After the fluid had been removed and more bone rongeured away for decompressive purposes, the wound was closed without drainage. The patient recovered from the operation, but his condition was not improved. At a second operation a large osteoplastic flap was turned down in the right frontoparietal region. On incision of the dura the cortex was found to be covered by an organized blood clot 0.5 cm. in thickness, which had evidently compressed the parietal and frontal lobes. This layer of organized tissue was removed, when the brain began to expand and pulsate, and was found covered by newly-formed blood vessels. The dual incision was closed by interrupted sutures and the bone flap returned to place. The patient gradually recovered in every particular. This case is recorded not only because of the unusually satisfactory operative results, but also because the mental symptoms were evidently the result of the involvement of the frontal lobe. None of those who witnessed the operation had ever seen so large a clot removed from a living subject. It is probable that it was produced by oozing since an initial hemorrhage of the size indicated by the clot would have proved instantly fatal.

4. Afterthoughts of the Epidemic of Infantile Paralysis. — Beverley Robinson writes that we are still obliged to confess our ignorance as to the cause of infantile paralysis and to fall back on the time-honored statement that an epidemic influence has prevailed. The proof of this assertion is that cases appear suddenly in widely separated tracts of country; that in some cases children, young men and women, and occasionally adults of a certain age have been attacked; that not infrequently there is no evidence that a possible human carrier of the disease can account for it; that healthy children who are most carefully looked after take the disease and not merely neglected children. No system of quarantine has prevented the disease from attacking persons at a given time. In all these particulars and in others it is closely allied with the grippe. So far as many symptoms are concerned it also resembles the grippe more closely than any other known affection. So far as precautionary measures are concerned there is no reason to change what is rational in the case of both diseases. By intelligent treatment the worst effects of infantile paralysis may be warded off and, in the opinion of the essayist, this intelligent treatment consists in the internal use of ammonium salicylate, supplemented by the local use of carbolated petrolatum introduced into the nares night and morning. The employment of immunized blood serum injected into the spinal canal has been of great service, but should be given only by an expert. Ammonium salicylate has been very valuable in the treatment of grippe and much may be hoped for from its wider use as both a preventive and a curative measure in poliomyelitis.

5. Pelvic Massage.—Ferdinand Herb reviews the history of pelvic massage in gynecological cases and discusses the reasons why it gives brilliant results in the hands of some gynecologists, while others fail entirely to obtain any benefit with this method. Massage should be as useful in removing remnants of inflammatory conditions, improving local circulation, freeing nerves, blood vessels, or organs imbedded or distorted and displaced by cicatricial tissues in the pelvis as it is if such afflictions are near the surface of the body, or where they are easily accessible. The principal reason why pelvic massage is not successful in the hands of some gynecologists is because the length of the fingers falls below a certain measure. The varying length of the fingers of the different physicians will alone explain much of the difference of opinion apparent in the literature on pelvic massage. To provide for definite figures as to the length of fingers necessary for pelvic massage, the writer states that his own middle finger is three and fifteen-sixteenths inches. This is decidedly more than the average length. Dr. Robert Ziegenspeck of Munich, one of Europe's most ardent advocates of pelvic massage, has fingers slightly longer than the writer, while Thure Brandt, who first achieved such remarkable results by the employment of pelvic massage, had much longer fingers than Ziegenspeck. As it is important if justice is to be done to these cases that physicians be trained in pelvic massage in post-graduate schools, it is essential to select from the applicants for tuition only those who have the proper physical as well as scientific qualifications.

7. Rectal Operations Under Local Anesthesia. —J. F. Saphir reports a series of nineteen rectal cases operated on at the Gouverneur Hospital under the local influence of quinine and urea hydrochloride solution, all of whom were relieved of their rectal ailments, without inconvenience either during or after the operation. They were all able to leave the clinic immediately to attend to their usual duties. He does not hold that all rectal cases should be operated upon under local anesthesia, but maintains that about 75 or 80 per cent. of hemorrhoids, external, internal, and thrombotic, rectal polypi, fissura ani, anal ulcers, dermoid cysts, tight or hypertrophied sphincter ani, skin tags, some cases of fistula ani, and some cases of prolapsus ani, can and should be operated on under local anesthesia. The cases reported prove that rectal conditions can be cured under local anesthesia and that the patients need not be confined to bed, a matter of importance from an economic point of view, both to the individual and the hospital. The method is suitable for patients suffering with pulmonary tuberculosis, nephritic, or cardiac diseases.

1. The Problem of the Chronic Cripple.—Russell A. Hibbs says that as the knowledge of the fact that there are a large number of people in every community who need orthopedic care increases, and as methods of treatment are perfected, a large number of men are going to select orthopedic surgery as their specialty. As a result of inquiries of various clinics in different parts of the country, it has been shown that the percentage of patients admitted to the hospital for operation of the total number treated in the dispensary varied from 3 to 10 per cent. The average for the whole number was 10 per cent. Thus the large proportion of orthopedic cases are chronic ones and require on the part of the surgeon a chronic enthusiasm. Such enthusiasm is of slow growth and suggests that the orthopedic surgeon, as compared with the general surgeon, should have a longer period of preparation. It would also seem that if a man's training is only in the hospital, his preparation for the treatment of the 90 per cent. of patients who never enter the hospital is poor. There is a great deal more written about the 10 per cent. who need operations than about the 90 per cent who never enter the hospital, and herein lies a danger to the development of this specialty. There is no question of the importance of the operative work, but the non-operative should not be neglected. With the proper training of the orthopedist comes the question of the best means of applying it to the cripple. There are many communities throughout the country in which such work is new and such places offer wonderful opportunities for men to initiate organizations ideally fitted to the need of the cripple, unhampered by the difficulties of attempting to do the work for the cripple in a small orthopedic department in a general hospital, the spirit and atmosphere of which is not helpful to work of this kind.

5. Syphilis as a Probable Factor in Vague Stomach Disorders.—Cabot Lull. (See MEDICAL RECORD, July 1, 1916, page 34.)

6. Syphilis in the Southern Negro. — H. L. McNeil. (See MEDICAL RECORD, July 1, 1916, page 34.)

8. Health Insurance in Its Relation to Public Health.—I. M. Rubinow shows that while compulsory health insurance must necessarily be limited to wage workers or salaried persons, voluntary health insurance may be encouraged with advantage among other social groups. He states that the effect of the money benefit is evidently not limited to relieving misery and destitution for the time being, but is even more important in giving a better chance for recovery. The failure to understand the difference between "disability" and "inadvisability to work," has caused many critics to deny the preventive feature of sickness insurance in Germany. It is pointed out that the health conditions in Germany could not have improved because the average amount of sickness disability has increased; as a matter of fact, this indicates an increase in the days of inadvisability to work, or in other words, a very much improved care of the sick. It is obvious that the success of health insurance depends on the effectiveness of medical aid. A system of medical aid which fails to provide for team work, which interferes with any degree of medical organization, either because of considerations of economy or because of conservative clinging to old standards, will utterly fail to make health insurance a powerful fulcrum for lifting general health conditions. Whether medical aid under health insurance will accomplish all that it is capable of depends on such details as availability of consultant and specialist; arrangements for hospital care; additional care for convalescents, and a liberal provision for drugs, appliances, etc. It must be admitted that a capitation system of payment for the medical profession, whether small or large, has in it inherent tendencies for slipshod careless medical work, and neglect of those patients who need aid more frequently. The writer points out that good sickness statistics are not an automatic result of health insurance, and that they cannot be perfected without the willing co-operation of the medical profession.

9. Health Insurance: Its Relation to National Health.—B. S. Warren suggests that it would seem feasible under our form of government to provide a system of health insurance for interstate employees by federal law and for intrastate employees by state law. To be adequate as a public health measure, a health insurance system should provide for: (1) Adequate cash and medical benefits to all wage earners in times of sickness and death. (2) The distribution of the cost of sickness among the groups responsible for conditions causing disease, viz., the employer, the employee and the public. (3) The stimulation of the co-operative efforts for disease prevention on the part of the responsible groups named above and the linking of their efforts with existing health agencies. (4) The correlation of the work of all agencies working for the relief and prevention of disease. Such a law, if enacted by the federal and state legislative bodies, would have two distinct relations to the national health. It would operate as a relief measure by providing relief for all cases of sickness in this group and thereby would have a decided effect in improving the health of the people. It would operate as a preventive measure by fixing a definite price for each day lost on account of sickness and by providing a financial incentive to those paying this price by preventing sickness; it would start a movement for preventing disease, just as certainly as the workmen's compensation laws have brought about the nation-wide "safety first" movement. Properly coordinated with existing health agencies, the machinery would be ready at hand for advising and directing this movement with respect to disease prevention. In view of the experience in both Europe and America, it would seem best to place the administration of the medical benefits directly under governmental agencies, and to insert a provision that no cash benefits be paid except on the certificate of medical officers of the national or state health departments acting as medical referees under the regulations of the central governing boards. Such medical officers should be selected under civil service methods, and appointments should be based on a knowledge of preventive as well as clinical medicine.

10. Some Bacteriological Observations on Epidemic Poliomyelitis: Preliminary Report. — George Mathers has made cultures from the brain and cord of fatal cases of poliomyelitis. In seven or eight cases thus far examined bacterial growth developed in aerobic ascites dextrose broth and agar cultures after eighteen hours,

while in the anaerobic cultures made according to the technique of Flexner and Noguchi, a definite growth usually did not appear until after from three to seven days, and then often very scantily. In six of the seven instances a pure culture of a gram-positive micrococcus was obtained. In one instance the culture gave also a gram-negative bacillus. On blood agar plates the organism grows in small dry colonies, which produce a faint green halo and a slight degree of hemolysis. Cultures from the heart blood and from the cerebrospinal fluid after death thus far have not yielded this micrococcus, but it has been obtained from the mesenteric lymphnodes. The organism is of low virulence for rabbits, but when injected intravenously in large doses lesions of the central nervous system are produced, with paralysis which may resemble that of infantile paralysis, especially as it affects the extremities. Intracerebral injection of the organism soon after isolation has produced paralysis in the monkey. The author thinks that in view of the accepted facts in regard to the virus of epidemic poliomyelitis it would seem most reasonable to regard the micrococcus described as a secondary invader, but that further work is necessary before its significance can be fully understood.

1. An Address on the Analysis of Living Matter Through Its Relations to Poisons. A. R. Cushny.
2. Contributions to the Study of Shell Shock. Being an Account of Certain Disorders of Speech, with Special Reference to Their Causation and Their Relations to Malingering. Charles S. Myers.
3. The Effect of Trench Warfare on Renal Function. J. W. McLeod.
4. The Diagnostic Value of Tubercle of the Choroid. Sidney Stephenson.
5. Trench Pyrexias: Their Prevention and Treatment. Basil Hughes.
6. On the Dressing of Septic Gunshot Wounds. W. B. Davy.
7. The Schiah Pilgrimage and the Sanitary Defences of Mesopotamia and the Turco-Persian Frontier. (Concluded.) F. G. Clemow.

2. Contributions to the Study of Shell Shock.—Charles S. Myers gives an account of certain disorders of speech, with special reference to their causation and their relation to malingering. The principal disturbances of speech which he has encountered may be grouped under three heads—aphonia, dysarthria and mutism. This is the order of frequency in which, from our experience of functional disorders in times of peace, such disturbances of speech might be expected to occur. In the class of cases occurring in war the order has been exactly reversed. Dumbness is by far the commonest disorder of speech, occurring in about 10 per cent. of all cases of shock which have come under his notice. He has met with affections of articulation, stuttering or jerky speech, only in about 3 per cent.; while loss of voice, as the result of shock, is of somewhat rarer occurrence. In about one-third of the cases of mutism caused by shock various predisposing affections may be demonstrated, such as nervousness, fits, stuttering, wounds, or exposure to the enemy's gas. These disorders of speech are not immediately due to physical causes, but are the result of a functional inhibition, arising primarily from disorder in the personality; they are not due to some fixed idea of paralysis. These functional disorders are apt occasionally to simulate malingering just as at other times they simulate organic lesions. About 75 per cent. of the cases of mutism improve rapidly while the remainder are slower in making a recovery. In the treatment of these patients, psychotherapeutic measures, that is, suggestion, persuasion, and encouragement, have been employed with success.

3. The Effect of Trench Warfare on Renal Function.—J. W. McLeod has made a study of over 4,000 British and French troops with reference to the effect of warware on renal function, with the hope that some reason might be found for the frequency with which acute nephritis has been observed during the present war. He concludes that exposure alone probably has nothing to do with the causation of a number of cases of nephritis observed in France, especially the milder ones, and that if it has a part in the etiology of the severer ones it will be similar to that exhibited in many infectious diseases, namely, that of setting up a defective circulation in an organ so as to render it less capable of resisting infection. The majority of the transitory albuminurias so common among the troops can be classed with the so-called "fatigue" albuminuria. There exists, especially among the British troops, an excess of cases of symptomless albuminuria, apart from those just mentioned, which cannot be classified as chronic nephritis. Diet appears to be the most likely explanation of this excess of transitory albuminuria and mild nephritis, and may also contribute toward the development of the more severe cases. It has been shown that the average soldier is consuming an amount of protein food in excess of his requirements, and is therefore throwing an undue strain on his excretory organs. This statement is confirmed by the numerous cases of gingivitis coming under observation, which probably indicate that the men are suffering from a restriction of fresh vegetables, which is usual and inevitable for troops in the front line. The resistance of the kidney, in common with other organs, is lowered by a slightly scorbutic condition, and gives out when, in addition to this, it is required to make an excessive metabolic effort, owing to a high protein diet, or is exposed to bacterial intoxication, either by direct invasion or by the establishment of an infective focus in some other part of the body.

4. The Diagnostic Value of Tubercle of the Choroid.—Sidney Stephenson thinks there is a tendency in modern times to overlook the general diagnostic value of tubercle of the choroid. He reports three cases which have come under his notice within a few months in which an acute tuberculosis was diagnosed as such by the discovery of tubercle of the choroid. In one the diagnosis was made from an apical pneumonia; in another, from a pneumococcal peritonitis, and in a third, from typhoid fever. The finding of these three cases within so short a time lends truth to the statement that acute tubercle of the choroid is by no means an uncommon manifestation if looked for in the right places and in the right way. A more frequent ophthalmoscopic examination of children in hospitals would prove a great aid in diagnosis.

5. Trench Pyrexias: Their Prevention and Treatment.—Basil Hughes writes that during August, 1915, and the succeeding months, "pyrexia" was of common occurence among officers and men living in the trenches. The diagnosis given in these cases was pyrexia, not yet diagnosed. A noticeable feature during the later months of the year was the rapid spread of this pyrexia when once started. With regard to its causation there are the following facts: (1) The occurrence of the disease was greatest during the time that conditions in the trenches were worst. (2) On getting back to clean huts in the rest billets, where the men could get a bath, a clean change of underclothing, and could have their uniforms and blankets disinfected, the number of cases fell immediately. (3) On coming away from trenches for a month to a place where personal hygiene could be thoroughly carried out it was a simple matter to eradicate it. There is, therefore, strong presumptive evidence that this is a louse-borne disease, for whenever it was possible to carry out measures for the eradication of lice the number of cases invariably fell

to a minimum. A possible explanation might be found in the trench rat, which lives largely on decomposing organic matter. The first step in prevention of the conditions seems to be eradication of the vermin. The drugs which have proved effective when the disease has established itself are quinine and sodium salicylate, administered after an initial purge.

Ocular Lesions Due to Tear-Producing Gas. — Gremeaux describes the symptoms and treatment of these cases as follows: When brought in wounded the eyes show photophobia and lacrymation and the lids are swollen and reddened, as a result of rubbing. The conjunctiva is injected finely, giving it a pinkish tint. Shortly after exposure to the irritating gases the cornea shows at its periphery a very fine exfoliation of the epithelial layer; this phenomenon is present even in the milder cases. There is an absence of secretion in the lower cul-de-sac. After a stationary period of several days the condition slowly recedes, although some lacrymation and photophobia may persist for three or four weeks. If, however, the eyes were already the seat of an infection of the lacrymal passages the erosion of the corneal margin is more marked. The application of an occlusive bandage also emphasizes the conjunctival reaction to the smoke and favors infection, corneal ulceration, etc. Treatment consists in irrigation of the eyes with oxycyanide of mercury 1-6000, the instillation of atropine 1-200 up to full dilatation, and the instillation of 1 per cent. zinc solution. An occlusive bandage should, of course, be omitted. Instead, poultices of potato flour are recommended. A very loose dressing, sufficient to exclude light, will serve when poulticing is discontinued. No cocaine should be used. During nine months the author treated 47 ambulance cases, of which 28 were mild, 2 aggravated, as result of preceding infection of tear passages, 3 aggravated by wearing an occlusive bandage. There were 14 clean recoveries. The duration of exposure to the gas appears to make no difference.

Phlegmons Produced by Injection of Gasolene.—Dillenseger in a recently published thesis (Lyons) gives an account of two of these cases and cites a number of others. The subject is a new one, the first report coming in 1915. The production of these phlegmons is classed as a criminal procedure, as it is a matter of simulation to avoid military duty or to secure a pension. The question of diagnosis is all important. A section through one of these phlegmons much resembles a section through a carbuncle. The pus which exudes is, of course, sterile. Decoloration of bromine water by the gasolene in the pus is the chemical test. Pyrexia is practically absent. But despite all these resources for diagnosis it is probable that in certain cases the artificial nature of the condition is overlooked.

Cure of Hard Edema Due to Trauma and Phlebitis.—Denis reports cures of this affection as a result of hypodermic injections of eau de Breuil, of which he has now made some 2,000. This water is known to be pure and sterile, and not one abscess resulted from the treatment. It can be drunk very freely for weeks without inconvenience. There was no definite relationship between the amount of water used and the duration of treatment. The water may be classed as of a sodium bicarbonate-ferruginous type. The water is drunk as well as injected, but cannot be pushed in hypertensives or in those with weakened circulation. These military cases seem to be more amenable to treatment than simple hard edema in civil practice. The treatment is extremely simple, as the water may be injected directly from the bottles. The usual quantity injected is 0.40 c.c. and the rest of the bottle is drunk. In the cases treated there was no other form of treatment used—neither massage nor rest. The location of these hard edemas, notably about the ankles, makes radiography of service, for the reduction in size of the soft parts is readily apparent.

Treatment of Typhus with Colloidal Metals.—Bouyges saw typhus in Serbia, having cared for 150 patients. Some plan became necessary for the routine treatment and from analogy the colloidal metals seemed worthy of a try-out since typhus is clearly a sepsis. Further intravenous injections of colloidal silver have seemed to do good work in typhoid. An intravenous injection of 10 c.c. causes no typical results save that of a sense of subjective improvement. Objectively some of the patients showed favorable modification of the disease. If a chill developed it was brief. Colloidal gold, however, provoked a reaction comparable with a severe malarial crisis and is not to be thought of as a remedy. Colloidal silver in the absence of a serum is perhaps the only known remedy which exerts any favorable influence on the disease. In so-called recurrent typhus both metals seem to give results, especially colloidal gold, which should be begun cautiously in small doses.

September 11, 1916.

Periodical Vomiting with Acetonemia Versus Appendicitis.—Marfan does not believe that these two conditions have any necessary connection. The former is a disease of early life and seldom occurs after the age of ten years. The crises of vomiting appear to have the effect of ridding the body of some catabolic product which acts on the vomiting center. These emetizing substances may be the result of defective formation of fatty acids by the liver. Intermediate products of the Ketone series are formed as a consequence of insufficiency of the latter. The entire process is analogous to chloroform poisoning. There is a marked predisposition, the children being of the neuro-arthritic type and a diet rich in fat may be a contributory cause. The author now relates twenty-one cases in which each patient had submitted to appendectomy before developing the crises of vomiting with acetonemia. As the appendicitis was usually of a mild course the possibility of error of diagnosis at once suggests itself. That is the "appendicitis" for which appendectomy had been done was in reality the earlier crises of the vomiting with acetonemia, and removal of the appendix was naturally without effect on the course of the disease. Ordinarily differential diagnosis is easy, but it may be difficult and even impossible. In the crises of vomiting the region of the appendix should always be palpated, but the physician may neglect this precaution. In acute appendicitis there is considerable fever. In the same affection acetonemia may happen to be present as a result of inanition, due to the disease. There is usually meteorism with appendicitis, while a flat or concave belly is the rule with cyclical vomiting (the latter may simulate meningitis). Tenderness, hyperesthesia and muscular defence are never present. But even the most careful research for appendicitis may give equivocal results, as very slight rigidity and doubtful pressure pain, while acetonemia may be a precocious and notable feature. A possibility which should be borne in mind is that of a coincidence of the two diseases in one subject.

Le Caducée.

An Ocular Compressor for the Oculocardiac Reflex.—Roubinovitch describes the now well-known Aschner phenomenon in which compression of the eye can be made to cause changes in the cardiac rhythm. In the normal individual there results a slowing of the heart beat of from four to ten pulsations, while in many pathological states the rhythm is distinctly altered; bradycardia or acceleration may be produced. Hitherto the clinician has made compression with his fingers, or, rather, an assistant compresses the bulb while the clinician investigates the rhythm of the heart. At times three persons are required to make the test. Hence the need for some mechanical device which will replace the individual. Such would have to be absolutely painless, supple, regular, measurable, durable and aseptic. The base of the author's device is an ordinary spectacle frame with frontal, nasal and ocular attachments in which coaptation is accurate. Pressure on the eye is effected by an automatic mechanism which admits of perfect control, so that any degree of compression may be obtained, and afterward maintained by a spring device. Through the use of this compressor all the results of digital compression have been verified. In epileptics the reflex is expressed in the great majority of cases by an acceleration of the pulse rate.

Simulation of Deafmutism for Five Months.—Berruyer reports a case of apparent deafmutism in a young soldier, said to have been due to a great shell explosion. In consultation the man seemed to be an absolute deaf mute. Before the explosion his speech and hearing were normal. He was at once told that he would recover. Several days of closest watching showed no evidence of simulation. The patient was then placed in a state of semi-narcosis with chloroform, and in this condition conversed without difficulty. A dressing was applied to his throat for the psychic effect. Afterward he admitted recovery but showed no normal delight over his apparent good fortune. His former physician was consulted and stated that he had treated the man for six weeks by reeducation and had left the hospital perfectly cured. The writer leaves us in some doubt as to whether the original attack was simulated, but doubtless it was genuine, as he was under the charge of a competent neurologist. After this experience he must have thought of deliberate malingering in order to keep out of the fighting line, for recovery from shell shock of this type within the army zone is notably tedious and uncertain.

Le Bulletin Médical.

September 5, 1916.

On Refusal by Soldiers of Operations Recognized as Necessary.—Janicot relates that this question was first started in connection with certain electrotherapeutic procedures, but is seen to apply to many surgical operations which have been formulated under three heads by the Direction of the Sanitary Service: (1) Refusal to submit to a legal prophylactic prescription like vaccination; (2) refusal of a nonbloody intervention, and (3) refusal of a bloody intervention. It is recognized that some surgeons are naturally timorous and hesitate to go ahead with measures which they feel are heroic. Others are not timid or hesitating, but doubt their right. These attitudes on the part of the profession tend to invalidate routine procedure, and it is happening more and more that necessary measures are withheld. Some soldiers even refuse to allow their stiffened joints to be mobilized. Others object to the extraction of small sequestra of bone which alone prevent the healing of fistulæ. Others, again, will not consent to the removal of projectiles from the tissues, although they may be causing them inconvenience. Those badly injured never refuse treatment, but the slightly injured think things may go worse for them. Sometimes they distrust the ability of the surgeon on duty or fear that they will be interned in hospital until the end of the war. Various learned bodies have rendered opinions. The Medico-Legal Society states that refusal is not a positive fact in law, such, for example, as is deliberate mutilation. A wounded soldier cannot obtain positive assurance as to the outcome of a given procedure. The doctor cannot even guarantee that the patient may not be worse off, or that he may not even die after the intervention. A debate by the War Council with a defense of the right to refuse would be sure to bring out differences of opinion. Who would then decide the matter? Not the judges, who would be unable to decide which views were correct. Nor could an expert or technichian be able to decide as he is not above criticism. Another opinion was rendered by the Commission of Public Hygiene of the Chamber of Deputies, as follows: If the wounded is rendered unfit for medical service and if operation can diminish his infirmity the benefit which thereby accrues will have to be charged against his pension claim. If the treatment or operation refused could make the disabled man fit to resume military service, he shall by no means be maintained in a hospital, but put to some work in the rear, in accordance with his disability without leave of absence. At the close of the war he should be mustered out, but should not receive a full pension. Any gratification sought would have charged against it the benefit he should have derived from the operation. Professor Hartmann, representing a Subcommission of the Superior Consulting Commission, makes the following report: Refusal to be vaccinated against smallpox, typhoid, etc., is a breach of discipline and punishable, because these officers are backed by the laws. Refusal to be treated for syphilis is a breach of discipline and the man must be penalized. Those ill with nervous disturbances comprise many malingerers and must submit to diagnostic tests of all kinds. All nonbloody interventions must be submitted to, including hydrotherapy and electrotherapy. Retentive apparatus must always be worn when necessary. In all such cases narrated above the soldier has an expert opinion, which does away with prejudice toward the regimental surgeon. On the other hand, a soldier can protest against the removal of an eye, testicle, hand (even a thumb), but everything must be done formally and in writing. If the operation refused is nonmutilating, the reasons for refusal must be asked and the injured must be informed as to the effect of nonsubmission on his pension. But if it is decided that recovery is practically certain the soldier may be forcibly operated on for the common good. Such a step is carefully determined in advance by a medicolegal commission. Absolute refusal to submit to treatment in the face of all these precautions must be regarded as a breach of military discipline.

Night Terrors.—Williams regards night terrors as analogous to the phobias of older persons and quotes a number of cases in which the symptoms could be traced to definite incidents in the child's experience or to injudicious education or treatment. He advises not exactly a psychoanalysis after the method of Freud, but a careful interrogation designed to lay bare the root of fear. If this is successfully attained no further treatment may be necessary, but in some cases the child benefits by a sympathetic explanation of the symptoms, a process of re-education, and exercises in mental concentration.—*Edinburgh Medical Journal.*

Book Reviews.

THE PATHOLOGY OF TUMORS. By E. H. KETTLE, M.D., B.S., Lond., assistant pathologist, St. Mary's Hospital; assistant lecturer on pathology, St. Mary's Hospital Medical School; formerly pathologist to the Cancer Hospital, Brompton. With 126 illustrations. Price, $3. New York: Paul B. Hoeber. 1916.

THERE has been in English no very satisfactory book of moderate size on the subject of the microscopical structure of tumors, since the excellent volume published by Powell White some years ago is concerned rather with the general biology of tumors than with their histological details. This volume of tumor pathology, however, covers the field very well. There is no pretense that it is an exhaustive reference work on cancer; it is intended rather as a student's text, not only useful to the beginner in tumor pathology, but also of great interest and value, to the surgeon who wishes to fit himself for the intelligent practice of his trade in that phase which has now become of such importance, the operative treatment of tumors. Unfortunately, at the present time the surgeon regards anatomy as of much more importance than pathology, so that he is more apt to operate on a tumor from an anatomical point of view than from a pathological, with the result that the statistics of operative surgery on malignant tumors show that the accomplishments of many individuals and hospitals are not as yet commensurate with our knowledge of the nature and metastatic distribution of tumors. There is still, even in the large cities, too much partial surgery of malignant growths, with the inevitable result of early and inoperable recurrence. The first part of this book gives a very good review of the general biology of tumors, full credit being given to the recent admirable work of the Imperial Cancer Research Fund in London. In his discussion of the value of frozen section diagnosis, the author, in his anxiety over a possible error by the pathologist, seems to lose sight of the fact that it is better for the patient to undergo an extensive operation for the removal of a benign growth than an incomplete operation for the removal of a malignant one. In the first case, the patient has had possibly a serious operation, but still remains a useful member of society; in the second, death is inevitable. There are many growths which it is impossible to diagnose from their gross appearance, and we can get the best results in the treatment of carcinoma only by frozen section diagnosis in the operating room, the pathologist being allowed to state from what portion of the material he desires a specimen, for very few surgeons have sufficient laboratory knowledge to enable them to select material suitable for microscopical examination. In the chapter on the classification of tumors, the author shows his self-control by refusing to add a new classification to those already in existence. Part III, devoted to special pathology, is a little too compact; one wishes that the author had seen fit to furnish more details. Bibliographical references have been omitted entirely, which is a matter of regret, also, because of the limitations which it places upon the use of the book; but presumably space did not permit the inclusion of what would have made the book more valuable. The illustrations are exceedingly good, and color has been used very effectively to bring out certain points. The index, also, is very satisfactory. Altogether the volume can be highly commended both to the students and to the practitioner of surgery as the best text in English on the subject.

BEING WELL-BORN, An Introduction to Eugenics. By MICHAEL F. GUYER, Ph.D., Professor of Zoology, The University of Wisconsin. Childhood and Youth Series. Edited by M. V. O'SHEA, Professor of Education, The University of Wisconsin. Price, $1.00 net. Indianapolis: The Bobbs-Merrill Company, 1916.

HEREDITY and the part it plays as a direct influence and factor in our lives is still a mooted question among the philosophers of the varied sciences. Professor Guyer has given us a book that is more than a compend and less than a complete text-book on the subject of heredity, environment and eugenics, and the interrelation of each to the other. To those not well acquainted with his topics, the book is somewhat confusing and even for those with a reading knowledge of his material there is a demand for very careful, intelligent study of his text due to the difficult subject matter. Since there is so much yet to be learned on this subject the author naturally has matters very much his own way. He quotes Professor Pearson as stating that statistics show that heredity is five or ten times as important as environment in the development of the individual. The book is intensely interesting and is an evidence that the author is thoroughly conversant with his subject as far as research has opened up this bewildering, but fascinating study.

MAKERS OF MODERN MEDICINE. By JAMES J. WALSH, M.D., Ph.D., LL.D., Litt.D. (Georgetown); Sc.D. (Notre Dame); L.H.D. (Catholic University) Professor of Physiological Psychology at the Cathedral College, New York; Sometime Dean and Professor of the History of Medicine and of Nervous Diseases at Fordham University School of Medicine; Member of the French, German and Italian Societies for the History of Medicine, N. Y. Hist. Soc., N. Y. Acad. Med., A. M. A., A. A. A. S., etc. Catholic University Edition. Enlarged by the addition of the life of Virchow. Price $2.00 net. New York: Fordham University Press, 1915.

THIS is the third edition of this work since its first appearance ten years ago, which is an indication that perhaps in due course of time a knowledge of the value of the study of medical history may be appreciated by students of medicine. Dr. Walsh offers a most delightful book containing the biographies of fourteen men who through original research have advanced by enormous strides the knowledge of medicine during the nineteenth century. He begins with Morgagni, father of pathology, and concludes with Virchow, father of cellular pathology, who is the one maker of modern medicine whom Dr. Walsh knew personally and intimately during a year spent in his laboratory in Berlin some twenty years ago. There is also included the Irish school of medicine represented by Graves, Stokes, and Corrigan. The presentation of the biographies is full of vital spirit and an impression is given that the author has not only a profound respect and admiration for these men, but a love for the work which he has so admirably written.

MONOGRAPHS OF THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. No. 6, January 31, 1916. TORULA INFECTION IN MAN. A Group of Cases. Characterized by Chronic Lesions of the Central Nervous System, with Clinical Symptoms Suggestive of Cerebral Tumor, Produced by an Organism Belonging to the Torula Group (Torula Histolytica, N. sp.) By JAMES L. STODDARD, M.D. and ELLIOTT C. CUTLER, M.D. New York, 1916.

THIS work is founded on the study of two cases of cerebral pseudotumor and is devoted largely to a comparison of torula infection with blastomycosis and coccidiosis. As a result the last named can be definitely excluded, as can also a majority of cases originally reported as blastomycosis. On the other hand, in certain cases reported under the latter head, the solution of tissue and production of gelatinous material in the brain, there was a marked resemblance to one of the authors. The second case, on the contrary, is still anomalous in its relationships.

THE DIAGNOSIS AND TREATMENT OF HEART DISEASE. Practical Points for Students and Practitioners. By E. M. BROCKBANK, M.D. (Vict.), F.R.C.P., Hon. Physician, Royal Infirmary, Manchester; Clinical Lecturer on Diseases of the Heart, Dean of Clinical Instruction, University of Manchester. Second Edition. With illustrations. Price, $1.25. New York: Paul B. Hoeber, 1916.

THIS is a concisely and clearly phrased small reference book for the use of students dealing with the elements of cardiac auscultation. In the second edition numerous additions and alterations have been made.

AIDS TO BACTERIOLOGY. By C. G. MOORE, M.A. (Cantab.) F.I.C. Captain 1st London Sanitary Company, Public Analyst for the County of Dorset and the Boroughs of Poole and Penzance, and WILLIAM PARTRIDGE, F.I.C. Joint Public Analyst for the County of Dorset. Third Edition. Price, $1.25 net. New York: William Wood and Company, 1916.

THIS is a third edition which has been thoroughly revised and considerably enlarged. It is a valuable little book dealing with bacteriology from various standpoints in a concise yet lucid manner. The question of the treatment of septic wounds is discussed and the relative merits of the methods in vogue at the war fronts are debated.

Society Reports.

THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Sixty-sixth Annual Session, Held at Scranton, Pa., September 18, 19, 20, and 21, 1916.

(Special Report to the MEDICAL RECORD.)

Tuesday, September 19—First Day.

THE PRESIDENT, DR. JOHN B. MCALISTER OF HARRISBURG, IN THE CHAIR.

THE Society met in General Session in the Ball Room of the Hotel Casey, and was opened with prayer by Rt. Rev. M. J. Hoban, Bishop of Scranton.

The Business Features of the Medical Society of the State of Pennsylvania. — Dr. CHARLES A. E. CODMAN called attention in his presidental address to the lack of influence in medical legislation exercised by the Medical Society of the State of Pennsylvania as evidenced in the passage of the Workmen's Compensation Act in its present form. To overcome this lack of influence it was suggested that meetings of the Committee on Public Health and Legislation be held in conjunction with similar committees of other medical organizations, and that there be also the co-operation of the State Department of Health and the Bureau of Medical Education and Licensure. Dr. Codman regarded as a matter of much importance the effort in the so-called Health Industrial Insurance Act to be introduced at the next session of the Legislature to secure legislation covering cases not provided for under the Workmen's Compensation Act. This effort he believed would result in the State Department of Health assuming the entire care of such patients. He further suggested the advisability of the Pharmaceutical Association and the combined medical profession uniting in an effort to secure legislation covering the disputed points in the Harrison Act. The plan of perfecting the organization of the State Society along lines similar to those of the American Medical Association, and of making the salary of the secretary-editor such that would allow him to devote his entire time to the work of the society, was suggested. Further suggestions included the establishment of an endowment fund; the practice of economies in the matter of fewer committees; the use of the one letterhead for the whole society; the appointment of a committee on archives which should prepare a history of the society for its coming seventy-fifth anniversary; the maintenance of the medical defense, medical benevolence funds, and the establishment of a unit of physicians and surgeons in each county toward national preparedness.

The society adopted the following recommendations contained in the address of President Dr. Charles A. E. Codman: The endowment fund at once voted $1,200 per year for this purpose; uniform society stationery, and the creation of a committee on archives. The suggestion regarding medical instruction of the laity was approved and referred to the committee on health and public instruction.

Election of Officers.—The following were elected: *President-Elect*, Dr. Samuel G. Dixon, Harrisburg; *Vice-President*, Dr. John B. Corser, Scranton; *Secretary-Editor*, Dr. Cyrus Lee Stevens, Athens; *Assistant Secretary*, Dr. Clarence P. Franklin, Philadelphia; *Treasurer*, Dr. George W. Wagoner, Johnstown. The place of the next meeting will be Pittsburgh.

The organization of a section on pediatrics was authorized by the trustees.

The legislative program to be favored by the society included bills for the regulation of the sale of alcohol and drugs under State supervision; for the amplification of the Harrison Act; amendments to the Workmen's Compensation Act; for a Milk Hygiene Law to safeguard the milk supply at the source by State inspection.

A Criminal Epileptic, with Consideration of Epilepsy as a Medicolegal Problem.—Dr. N. S. YAWGER of Philadelphia said that medicolegally the mental manifestations of epilepsy were divided into two groups: (1) Paroxysms in which the individual is not insane, but in which he may be irresponsible (*a*) irresistible impulses or impulsive acts; (*b*) the state of automatism; (2) paroxysms in which the individual is insane; these may be (*a*) acting under the domination of an insane delusion; (*b*) in a maniacal epileptic outbreak. The fact that epileptics are highly dangerous, despite long intervals of lucidity, made it desirable that the insane epileptic be committed by court procedure rather than by certificate. Report was made of a patient who had after six jail detentions been placed in a State hospital. The attacks in this case had been for the most part but momentary.

Dr. HUGH E. MEREDITH of Danville said that the mental condition in epilepsy was dependent largely upon the onset of the attacks. Long continuance of the seizures resulted in epileptic dementia. He did not believe that punishment should be meted to the epileptic mentally defective and irresponsible. Institutions for the insane were not in his opinion the proper places for the detention of these people. The various classes of epilepsy should rather be cared for in an institution in which special treatment might be received.

Dr. WILLIAM H. CARMALT of New Haven said that in the endeavor to meet legally the matter of the care of epileptics Connecticut had established for them a farm where, if needed, they might be kept for life. In his State also a fine of $50 was imposed upon a clergyman or justice of the peace performing the marriage ceremony for epileptics and the feeble-minded. So far, however, this legislation had been only a moderate deterrent.

The Care of the Indigent Insane. — Dr. CHARLES W. BURR of Philadelphia declared his personal conviction that State care of the indigent insane was the only efficient method of solving this problem, and he urged that the physicians of Pennsylvania use every effort to secure such legislation. Such State care, he believed, should be adopted as a permanent policy by the commonwealth, a certain proportion of the income of the State being appropriated to the care of the insane. In outlining a feasible working plan, he said there should be the appointment of a central board which should be responsible for the expenditure of all moneys. This board should be entirely separate from the Board of Charities. Each local hospital should have its own board of managers, to be appointed, however, by the central board. To the medical member of the central board should be referred the question of prolonged hospital treatment of a given case. Separate hospitals should be established for acute and chronic patients. Only by a study of the acutely insane could in Dr. Burr's opinion the cause of insanity be determined. Hospitals for this class of the insane should have highly efficient research workers. Such hospitals should be small and preferably in large cities. Hospitals for the cases of chronic insanity should also be small, but situated in the country and in combination with farms, thus giving opportunity for work which was often of great advantage to chronic patients.

Dr. CHARLES H. FRAZIER of Philadelphia endorsed Dr. Burr's plea for State care of the insane and referred to the work of the Public Charities Association in the interest of the State's dependent people. A survey made by this association had shown that in many instances county institutions caring for the insane were merely adjuncts to almshouses. The discreditable argument that it was cheaper to care for the insane in county hospitals could as well include the statement that it was cheaper to care for these people in the almshouse than in the county hospital. The statement that the rate of recovery was higher in county institutions was, in the words of Mr. Sydney Smith, more uncertain than statistics. He urged that the State Society, through its appropriate committees be prepared to introduce in the next Legislature the measures proposed by Dr. Burr, and that the county societies so familiarize themselves with the present conditions in the care of the insane that they may adequately instruct their representatives in Congress. Conditions prevailing in some of the institutions he declared to be actually inhuman, and called for immediate corrective legislation. A proposition made by the Public Charities Association in co-operation with the society's committee for the promotion of more efficient laws for the insane was submitted. Dr. Frazier referred to a resolution adopted by the State Board of Charities almost twenty years ago recommended that the State establish within reasonable time an institution for the care of all insane not cared for in private hospitals, and thought a "reasonable time" had elapsed.

Dr. OWEN COPP of Philadelphia, superintendent of the Pennsylvania Hospital for the Insane, said that the State alone could be reasonably expected to adequately provide for the medical treatment and scientific study

of the insane and mentally defective. The so-called economy of county institutions he regarded as delusive, in that the saving was obtained at the cost of appropriate medical attention and facilities for care and prophylaxis. In New York, Massachusetts, and in other states, experience had demonstrated the wisdom of the principle of state care of the insane. He believed that the colony idea in the care of the insane would eventually surpass the claims made by the advocate of the county asylum. He cited the case of a daughter of a syphilitic father who had died in a hospital for the insane. The patient presented the early stages of juvenile paresis. The mother and five brothers and sisters, upon examination, were also found to be infected. The case demonstrated the value of the medical and scientific spirit in the care of the insane, the neglect of which in this problem would prove a menace to mental health and racial soundness.

Dr. JOHN A. LICHTY of Pittsburgh said that of the nineteen to twenty thousand indigent insane in the State probably ten or eleven thousand were cared for in State institutions, the rest in county and municipal hospitals. The number of alcoholics found in county hospitals and frequently discharged as cured he thought was a factor in the claim that the county hospitals gave a higher rate of recovery. Just as by the State tuberculosis movement it had been possible to combat and in a measure prevent tuberculosis, there was needed a State organization for the care of the insane which would provide facilities for the treatment and prevention of insanity.

The Workmen's Compensation Law.—Dr. WILLIAM L. ESTES of South Bethlehem, chairman of the Board of Trustees, at the request of the board for suggestions for amendments to the act, submitted the following: (1) Define major operation as used in the wording of the act. (2) Extend the period of direct payment for treating the injured workman to thirty days. (3) Increase the limit of payment for "reasonable surgical, medical, and hospital services." A definition of "major operation" recommended by Dr. Francis D. Patterson at the request of the board for a definition Dr. Estes thought would in all probability be adopted by the Commission Board. In Dr. Estes' opinion the only efficient remedy of the present business error in the matter of proper fees, which apparently was the crux of the difficulty, was thorough organization through the county medical societies in demanding from insurance companies the same rate of remuneration which each physician is entitled to and accustomed to receive for similar services in his own community. It was to be remembered, however, that some of the clauses of the act were but tentative and that any claims by physicians should be made in a dignified manner; that while the law was primarily for the benefit of the workman, so far as possible without detriment to himself, the physician should assist in this work. To be borne in mind, also, was the probable enactment of a general social insurance law. It was in his opinion the physician's right to be consulted in the framing of such laws, and it behooved him to be on the alert for self-protection and for the common good.

Wednesday, September 20—Second Day.

FIRST VICE-PRESIDENT, DR. J. TORRANCE RUGH OF PHILADELPHIA, IN THE CHAIR.

What Can Be Done to Improve the Milk Supply in Pennsylvania?—Dr. L. A. KLEIN of Philadelphia presented this paper, in which he said that during 1911, 1912 and 1913 about one-fifth of the 190,000 dairy farms in Pennsylvania had been visited by inspectors of the State Live Stock Sanitary Board and classified as excellent, a small number; 30 to 40 per cent.; fair, 50 to 58 per cent., and bad, 8 to 15 per cent. Three groups were involved in any method of improvement, viz., the producers and distributors, the health officials and the consumers. The producers had found in recent years that many of the methods of improvement recommended for sanitary reasons were also good economically because they increased production, maintained the health of the cows, facilitated the work and prevented loss due to spoiled milk. Duplication of inspection by various authorities had not met with the producer's approval. Furthermore, he could not see why he should incur extra expense without a corresponding increase in the price realized for the sale of his product. The position of the distributor was similar to that of the producer. The economic conditions affecting the production of milk had driven many farmers out of the business. Shortcomings of regulation by local health boards were the great variation in regulations imposed, lack of scientific knowledge of the subject by such boards and the difficulty of getting qualified inspectors. Consumers were, as a rule, not sufficiently interested in the quality of milk furnished them. Comparatively few wealthy people bought certified milk. This indifference on the part of the consumer had made it possible for the careless producer to thrive. As reform measures there should be a uniform system of inspection in charge of the State, including grading and classifying of milk.

Dr. T. B. APPEL of Lancaster said that the milk supply of Lancaster was derived from 276 dairies and supplied to the consumers by 55 dealers. The Board of Health of Lancaster, as a member of which he had had experience, had divided the dealers into three classes: (1) Those who produced and marketed their own product; (2) those who marketed not only their own product, but who also bought new milk from other farmers, who did not have any milk routes, and (3) those who ran milk routes in town and had nothing to do with production. In addition, they had one large milk company which bought not only from their county, but also beyond its borders. The milk was examined at least once every two months by the city bacteriologist as to its physical characteristics and number of bacteria present. The average rating of repeated examinations considered with the annual dairy inspection brought out very markedly that the best milk and the best kept dairies were those belonging to those dealers who marketed their own product, while the poorest records were those of the dealers who simply had a milk route. Their attempts at grading and labeling milk had been violently opposed by the dairymen, and the public had not been educated sufficiently to be a factor in the case. It had to be admitted that with a proper number of qualified inspectors under the control of a central authority and governed by definite standards an ideal result would be obtained, provided always that the public could be sufficiently educated to support the project, but the inspection had to be continuous in character. He believed, however, that the Bureau of Health should control all food and milk questions rather than the State Live Stock Sanitary Board.

Dr. H. F. SMYTH of Wayne said that it was a matter in which he was very much interested and he would say that he lived in Radnor Township, to which Dr. Klein had referred. They had been classifying milk men in their community and they had found it working out very successfully. They employed a trained veternarian, who made a splendid dairy inspector. All their dairy scoring was done by this inspector. He had gone out with him a number of times and he did splendid work. They attempted to do as little policing as possible. All their efforts were on the educational line, and they had succeeded remarkably well. They had succeeded in getting the public with them largely. They published the scores of their dairies every three months in the local papers. They started first with simply publishing the better classes, but now they published the names of all classes. Their bacteriological tests were made by the State Live Stock Sanitary Board in Philadelphia. Their inspector worked in harmony with the laboratory. They preferred, though, to have their own inspection so they could have their own regulation.

Dr. G. B. HOLTZAPPLE of York said that very much the same conditions existed in York as in Lancaster. In addition to inspection it would be well to lay emphasis upon systematic instruction of both the producer and the distributor. If the State would supply printed matter which would explain to the farmers just how to improve their product and which could be preserved and consulted and studied, it would do much good. It would be looked upon by the farmers and distributors as authoritative. Articles were printed in the public press every now and then, telling how to improve the condition of the milk. He did not think the farmers would take to that nearly as well as if the State inspectors would supply literature so that they might glean what they ought to know, because it would be authoritative and there would be no question as to that.

Dr. W. S. GIMPER of Harrisburg said that in the paper by Dr. Klein it had been pointed out that 15 per cent. of the dairies examined were in the "bad class"; they could more properly be classed as horrible. Classifying these dairies as bad meant that all conditions were such that they could not comply with even the most moderate sanitary requirements, and that the milk pro-

duced and handled on the premises should be regarded as unwholesome. The dairies of the bad class comprised the most serious phase of the milk improvement problem. The owners were not amenable to suggestion or moral coercion; nothing but the heavy hand of the law would bring them to a realization of their crimes against public health. They were not only a constant menace to health, but were also a detriment to the entire dairy industry. Much time and effort had been spent in an attempt to educate this class of dairymen, with practically no good results. The improvement in methods to which Dr. Klein referred as "encouraging" had not been found among the "bad" dairies, but in those which were classed as fair and more largely those in the good class. This type of dairyman was usually ready and willing to make any reasonable changes which would tend to improve the quality of his products. Embarrassing regulations had, he believed, retarded rather than assisted improvement. A sudden increase of milk-borne diseases would stir a local board of health to activity, and drastic regulations which were far more esthetic than practical were adopted. The dairyman realized the hopelessness of complying with such regulations at the price he received for milk, consequently did nothing. Numerous investigations clearly showed that a large amount of milk was now being produced at a loss, and, if there was to be a general improvement in the milk supply it would involve an increase in cost of production which had to be borne by the consumer.

Dr. C. H. Miner of Wilkes-barre said that they, in Luzerne and Lackawanna Counties, got a large proportion of their milk from other parts of the State. What annoyed him was that a large part of the good milk from the farms in northeast Pennsylvania, along the route of the Lehigh Valley, went into New York City. It required certain standards, and all that good milk went in refrigerator cars to New York City. All that not inspected was shipped to Wilkes-Barre without refrigeration. The public health committee, through the co-operation of the State Live Stock Sanitary Board, had presented a resolution which would be voted on by the house of delegates.

Dr. J. B. Carrell of Hatboro said that he had been in the milk business himself. Unfortunately, he had happened to have a farm, and he had been up against the milk proposition, and he could say candidly that he would not give the product of the chickens scurrying around the farm for the product of twenty cows. That was an absolute fact. The idea of any farmer trying to produce hygienic or sanitary milk for 3½ to 4 cents a quart was out of the question. His suggestion was that to overcome the difficulty the city in which the milk was distributed should act as distributor, and it would be carefully considered and provision should be made for the farmer or the producer of the milk to see that he got an honest and fair price for his milk.

Carriers.—Dr. H. J. Benz of Pittsburgh presented this paper, in which he said that if the carrier was found and excluded from school one of the problems of school infection would be solved. The carrier, except in diphtheria, was most difficult of detection, but in most cases a careful history and examination of those who had been absent from school would reveal the presence of infection. In respect to whooping cough all those with doubtful coughs should be excluded. In culturing for diphtheria in Pittsburgh schools the greatest number of positives were obtained in October and November. In school contacts 1.5 per cent. gave positive cultures; in home contacts this percentage was 3.4. Antitoxin has no effect on the life of the diphtheria bacillus. The various methods of disinfection of the throat in carriers were good only for their effect on the surface; if the tonsils were infected they should be removed.

Dr. B. F. Royer of Harrisburg stated that the system in use in Pittsburgh was well worthy of the attention of any who were actively engaged in medical school work. Dr. Benz had pointed out that in many of these chronic nasal and tonsilar carriers you got the germs of diphtheria. He might well have pointed out that the child recovering from scarlet fever having nasal discharge was apt to be a carrier of diphtheria or of scarlet fever. Public health authorities had long ceased to be much disturbed about the late desquamation in scarlet fever. Any child that had an extensive shedding of skin from any of the soaps used in the homes would have further flaking of that skin which would run over many weeks. He doubted if the attention of the profession had been sufficiently called to that point. The late shedding of the skin was perhaps not at all contagious, and he doubted whether it was at all so after thirty days. He would like to urge that medical men should not release from quarantine cases that had a discharging nose or running ears until they had been carefully studied.

The Significance of Hunger Pain.—Dr. J. W. Luther of Palmerton read this paper, in which he stated that in regard to hunger pain he was inclined to agree with Einhorn, who stated that Moynihan's symptom complex might occur with or without ulcer, and favored the theory that hunger pain was caused by a spasm of the pylorus induced by hyperchlorhydria, which was often associated with hypersecretion, and which was in a large percentage of cases complicated by a justopyloric ulcer. The causes of hypersecretion and hyperchlorhydria were too numerous to mention, nor did they directly apply to his paper. When "hunger pain and food relief" occurred with a painful pressure point and occult or microscopic blood in the feces, the roentgenological examination showed gastric hypermobility and a shortened duodenal cap and possibly also when Einhorn's string test, if used, was positive, a diagnosis of duodenal ulcer might be made, though many authorities claimed that even then it could not be accurate, and that a diagnosis of the position of the ulcer by the lateness of the onset of pain was impossible.

Dr. William H. Howell of Altoona said that hunger pain signified duodenal ulcer. This symptom meant corroborative evidence of such disease. It was not pathognomic, by any means, but helped to confirm one's suspicions. The *x*-rays and a careful and thorough history of the case were essential to a diagnosis. The symptom should never be drawn from the patient, but should be volunteered by him.

Dr. J. B. McAlister of Harrisburg said that as hunger pain was most commonly encountered in cases of duodenal ulcer it was a most valued symptom in the diagnosis of that disease. Yet pain which closely resembled it was often present when a patient was suffering from other affections. Hunger pain was not an accompaniment of any definite chemical state of the stomach. As a rule, hyperacidity was high, but even low degrees had been found. Hunger pain might be a symptom of acid gastritis, and was also found in catarrhal gastritis; also present in gastrectoptosis, enteroptosis, or nephroptosis. In hyperorexia, or parorexia, the sensation of hunger might become so intense as to amount to actual pain. Physicians were warned against making a diagnosis of gastric neurosis because a patient happened to be a neurasthenic. The patient might present the appearance and symptoms of a neurasthenic, and yet harbor a gastric ulcer or carcinoma.

Dr. J. A. Lichty of Pittsburgh said that he fully agreed that the etiological interpretation of this symptom was not clear, and thought the interpretation Luther had given was probably the correct one. There was one point which he did not believe he could agree with Dr. Luther upon, and that was that it was due to a hyperchlorhydria. Pylorospasm could be caused by other conditions than hyperchlorhydria. Mr. Moynihan's expression of some ten years ago that hunger pain was duodenal ulcer could certainly not be substantiated.

Dr. Ernest Laplace of Philadelphia said he thought that by common consent the pain described as hunger pain was usually contraction of the pylorus. We realized the intimate nervous connection, cerebrospinal and sympathetic of the nerves supplying the stomach. It was not to be wondered at that any irritation near by or at a distance resulted in spasm. He knew that, surgically speaking, he had almost never failed to find some sort of a lesion around the stomach, or even down as far as the rectum, when there had been hunger pain persistent.

Dr. Herbert B. Gibby of Wilkes-Barre said that there was no doubt that the most prominent symptom in ulcer was hunger pain. He could not agree with most of the former speakers that pains of this character meant only a duodenal ulcer. It might mean also a gastric ulcer.

Facts and Fallacies Concerning Electrotherapeutics.—Dr. W. L. Clark of Philadelphia read this paper, in which he said that progress in the use of electricity in therapeutics had been retarded by the ancient teaching that electricity was purely psychic in its action, the absence of teaching of the subject in the majority of medical schools and the prejudice which had arisen on account of the association of electricity with irregular practice. He would urge upon superenthusiastic electrotherapeutic advocates the necessity of being guarded in their claims and that teaching in electrotherapeutics

be established in all medical schools on the same plane as laboratories devoted to other subjects. Electricity, though always the same force, when modified with knowledge, intelligence, and skill, might be made to produce different effects, and it was upon this principle that the whole superstructure of electrotherapeutics rested. The effects produced by electricity might be classified as mechanical, chemical thermic, actinic, and psychic. Some of the future possibilities of electricity in therapeautis were the abstraction of metallic poisons from the body by ionization, safe local and general anesthesia, with loss of consciousness and relaxation, and relief of pain and the production of sleep, thus lessening the need of opiates.

Dr. H. C. Westervelt of Pittsburgh stated that there was no question among those who knew electrotherapeutics as to where the fault lay. The wealth of literature, unfortunately, did not exist in such form that the average general practitioner could avail himself of it. It was a special literature. Theologians stated that you could read anything into the Bible and read anything out of the Bible. It was the same with electrotherapeutics. There was an amount of definte knowledge which was readily available. The difficulty was that electricity was used by ignorant people. The practitioner came to these meetings, listened to the demonstrators of electrical apparatus, went home and tried it, and was disappointed and disgusted time after time until he lost all patience. It was up to the medical colleges to teach electrotherapy.

Dr. J. Torrance Rugh of Philadelphia said that the trouble was with the profession. He wanted to say that the trouble lay partially with the electrotherapeutists themselves, as had been shown more especially from the standpoint of reflexes. Electrotherapeutists spoke of curing cerebrospinal meningitis. How did they know they were doing it? They couldn't tell, because there were abortive cases of it. There were all forms of infection in between, and to make unguarded statements such as he heard from some of the electrotherapeutists was unwise. There was need for such an article as Dr. Clark had just given and for what he was doing to educate the medical profession. He thought there should be an educational propaganda for the general profession.

Dr. G. G. Davis of Philadelphia said that general medicine and surgery had occupied almost the complete field of our medical school teaching. The consequence was that the specialties were relegated to the background. We should bring them out and isolate them. Our graduates know about certain minute points in general medicine and surgery, but almost nothing about the common affections placed in the specialties. There was no reason why we should not have a chair of electrical therapeutics in the same way that we had of the other specialties.

Diabetic Gangrene.—Drs. John H. Jopson and E. H. Goodman of Philadelphia presented this paper, in which it was stated that judging from the favorable result of the treatment of diabetes by the Allen method was perhaps not too much to hope that, with careful consideration of every case of uncomplicated diabetes, diabetic gangrene might be prevented. They believed that diabetic gangrene was only a manifestation of an infection on the basis of lowered tissue resistance plus arteriosclerosis in most cases. There was, however, no specific organism of diabetic gangrene. The rational treatment of diabetic gangrene should be dietetic and local. Should the condition progress in spite of the strict observance of Allen's dietetic method, together with proper local measures, then the indications for amputation had to be considered. These indications were extension of the local process, with signs of septicemia and high glycosuria; or extension of the local process with signs of septicemia in the presence of acidosis. However, in the presence of septicemia even with low glycosuria, or sugar free urine, operation might be indicated. A high percentage of glycosuria in no way contraindicated operation, although it was better to reduce the urinary sugar if possible. When the local and general conditions became grave, operation should not be deferred. Their experience had shown that fasting should give place to free feeding some time before operation. They favored the use of alkalies in large enough dose to render the urine alkaline before operation and preferred to administer the bicarbonate of soda by mouth and by proctolysis. Water was given freely before operation and operation might be performed under local anesthesia. Ether and chloroform were contraindicated with patients having glycosuria.

Dr. M. Behrend of Philadelphia said that it had been his experience that results of operation after the Allen treatment had been far superior to any other form of treatment. There was another form of gangrene in diabetes. It was an insidious form of localized gangrene which occurred around the extensor tendons of the toes. It was a very grave symptom, and the prognosis in all these cases had to be very guarded indeed. Death resulted whether operation was performed or not.

Dr. Jopson said in closing that those who had the most experience would get a little hazy in regard to dietetic treatment before and after operation. His own experience was that patients prepared for operation with low fat-protein diet, in accordance with Councilman, stood operation well. He found that a patient put on starvation treatment in an attempt to get rid of the sugar developed acidosis and coma, from which she did not recover. Certain cases had convinced him that we had to feed cases until convalescence was established and the wound was healed. There was a certain amount of exhaustion which went with starvation, and we should feed until local reaction had been established.

Thursday, Sept. 21—Third Day.

Internal Secretions and Their Relation to Nervous Disorders.—Dr. Seymour DeWitt Ludlum of Philadelphia in this paper said that a study of nervous cases by their physiological symptoms pointed toward etiological factors which, considered with the morphology of the patient and with Abderhalden's reactions done on the blood serum for internal secretions, gave quite definite conceptions of backwardness, some forms of insanity, neurasthenia, dystrophies, etc.

Fecal Incontinence.—Dr. Samuel Goodwin Gant of New York divided the cause of fecal incontinence into nonoperative (brain and cord diseases, ulcerative proctitis, rectal cancer, injuries to the sphincters, etc.) and surgical groups. He believed the condition would become rare when surgeons acquired the ability to properly treat fistula-in-ano and ceased divulsing the sphincter rapidly with the finger and mechanical dilators and discarded Whitehead's operation for hemorrhoids. He had treated 25 patients for partial or complete incontinence caused by this latter operation. Non-operative treatment for fecal incontinence Dr. Gant regarded as useless in the majority of cases. A routine technique in surgical treatment was out of the question; the operation which would re-establish sphincteric control should be selected. The writer's operation, performed under local anesthesia, and in ten minutes, was fully described. Of 17 cases operated upon by this method fecal incontinence had been completely relieved in 9; diminished in 5; slightly reduced in 2, and no benefit had been observed in one. In cases in which the incontinence was the result of Whitehead's operation, or laceration of the sphincter from stretching by the fingers or instruments, cauterization was substituted for plastic operation.

Dr. Ira G. Shoemaker of Reading had seen pitiable cases of fecal incontinence resulting from lack of care in operations for fistula. With involvement of both sphincters he believed the best results were to be obtained by the use of elastic ligature. Although not advocated by the majority of men doing rectal work, he had used the method successfully many times. The ligature cutting through the tissues produced an irritation which formed a good base and promoted healing. The ligature adapted itself to the fibres of the muscle in the way of least resistance, which was squarely across. The muscle was severed or the ligature might be allowed to finish the operation. A case of purely psychic fecal incontinence which had been under his care was cured by suggestive means and placebos.

The Cooperation of Physician and Surgeon in the After-Treatment of Patients Operated Upon for Diseases of the Gastrointestinal Tract.—Drs. Edward H. Goodman and John Speese of Philadelphia presented this paper, which was read by Dr. Speese. In their opinion this cooperation should begin immediately after the operation. Even greater co-operation, they believed, indicated in cases surgical from the first in which the physician was consulted, but in which later the surgeon assumed entire charge. The medical attendant to whom a hospital patient returned from the hospital should be fully informed by the hospital physician of all facts relative to his condition. They condemned the routine prescription of diets employed in hospitals, regardless of the gastrointestinal conditions of the patients. The advice of the internist in a surgical case should be followed only with the sanction of the surgeon, and the mode

of living of such patients should be directed for from six to twelve months subsequent to operation. Lack of prolonged postoperative medical treatment, the authors observed, was given by Hamburger and Leach as a cause of absence of relief in operations for gastric and duodenal ulcer.

Dr. JOHN A. LICHTY of Pittsburgh believed that the co-operation recommended by Drs. Goodman and Speese should be not only postoperative, but operative and preoperative. While there might be opportunity for meddling on the part of the internist, some surgeons there were so dogmatic that cooperation was impossible. These two types, however, were not found in the ranks of reasonable men.

The Clinical Interpretation of the Wassermann Test.—Drs. JOHN A. LICHTY of Pittsburgh and JAMES H. WHITCRAFT of Wilkinsburg presented this paper, citing eight cases illustrative of a few points in the interpretation of the Wassermann test and calling attention to the fact that in only one of the cases had the patient any suspicion of his condition. This fact they had also found to obtain in many cases. The following summary was given of their cases: "(1) The Wassermann test, while not absolutely certain, is the most valuable laboratory aid in the diagnosis of syphilis. (2) A negative test in suspected cases should be repeated before the suspicion is dropped, often after a provocative dose of salvarsan. (3) A negative reaction may be due to previous treatment, which has not been curative. (4) The influence of specific treatment upon clinical manifestations of syphilis tends to show the reliability of the Wasermann test. (5) The existence of a positive Wassermann should not be construed to mean that syphilis is the only condition present requiring treatment."

Modern Diagnosis and Results, Clinically, Serologically, and Sociologically of Syphilis, Treated with Salvarsan and Its Substitutes.—Dr. B. A. THOMAS of Philadelphia presented a study of 510 patients in his private and hospital practice, and emphasized the importance of the heroic treatment of syphilis in its early stages. In the early diagnosis of suspicious sores he regarded the dark field illuminator indispensable. Among the conclusions drawn from his study the following points were noted: "(1) The treatment of syphilis remains empirical. (2) The ultimate proof of cure rests rather upon complete freedom of symptoms for a generation or more. (3) The Wassermann reaction furnishes the best control of treatment and is the most reliable index of cure subsequent to proper treatment. (4) The sheet anchor in the treatment of syphilis is salvarsan, neosalvarsan, or one of their substitutes. It is of paramount importance, however, that the injections of arsenobenzol, in the beginning, be administered as early as possible and intensively in full doses commensurate with the physiological tolerance of the patient. (6) Serologically, judged upon a three-month to a five-year duration, syphilis in the chancre stage, if diagnosed early, may be cured by two injections of salvarsan or neosalvarsan; if diagnosis be made before the advent of a positive Wassermann one dose of either of these drugs *may* be sufficient. (6) Secondary syphilis seems to do just as well without as with mercury, provided enough salvarsan or neosalvarsan be given to produce a negative Wassermann. (7) The best substitute for salvarsan and neosalvarsan is the Polyclinic preparation of arsenobenzol. (8) Sociologically, since only 10 per cent. of syphilitics return for hospital treatment until discharged cured, a problem is presented urgently demanding cooperation on the part of civil authorities and health boards for the control and treatment of this disease, not, however, to be realized until all hospitals receiving State aid are compelled to maintain evening dispensaries with paid attendants for the proper treatment, and admission when necessary, of venereal patients."

The Treatment of Syphilis by Salvarsan Controlled by the Wassermann Reaction.—Dr. JOHN D. WILSON of Scranton presented this report, based upon the study of 112 cases of syphilis seen in private practice in the last five years. His experience with these cases led him to the belief that salvarsan was most useful during the early active period of the disease, and that small, frequently repeated doses, namely, gram 0.3 to 0.4 every week or ten days for twelve injections, in conjunction with active mercurial treatment, should constitute the first course of treatment in any new active case. The after treatment should be determined by the return of suspicious symptoms and by the Wassermann reaction on the blood and spinal fluid.

Dr. GEORGE MORRIS PIERSOL of Philadelphia, in discussing the preceding three papers, stated that the chief result of the extraordinary advances in the study of syphilis in the past decade had been to show that spirochetal infection was the real cause of an ever-increasing number of conditions formerly not recognized as of syphilitic origin. It was to be remembered that the Wassermann reaction was not a primary but a secondary aid to diagnosis. In many of the more obscure visceral lesions of the nervous system, cardiovascular apparatus and in latent hereditary syphilis, very definite clinical manifestations might be present, and yet the blood Wassermann reaction be negative. Conversely, while a positive blood Wassermann reaction meant that a syphilitic infection was present, it far from proved that the condition present was due to this infection. For example, some enthusiasts regarded every case of chronic gastric disorder with a positive Wassermann as due to syphilitic infection. While syphilitic gastric ulcer was possibly frequent Dr. Piersol thought Fenwick correct in his conclusions that in about one-half of the cases in which the two diseases coexisted there was no direct relationship between them. Dr. Piersol stated that no apparently cured case of secondary lues should be discharged until spinal puncture had demonstrated the absence of involvement of the nervous system. Only in this way could early meningitis be recognized. He emphasized the inadequacy of the present equipment of the majority of State and hospital dispensaries for the treatment of active syphilities. The expense of their ultimate dependence upon the State might be almost entirely avoided by provision by the State for the control and scientific management of this class of patients. He believed that a cure could be pronounced only after a repeatedly negative Wassermann reaction for at least two years after a provocative injection of salvarsan and a normal spinal fluid. The persistence of spirochetal infection had been shown in the recent work of Warthin. Out of 41 cases autopsied in 11 of whom syphilis had been regarded as cured, 5 of whom har been under recent active syphilitic treatment and in 25 of whom syphilis had been clinically excluded, Warthin had found active syphilitic lesions and spirochetes in the tissues of all. In his work Warthin had also noted a relationship between glycosuria and diabetes and chronic latent luetic lesions of the pancreas.

Dr. JOHN A. KOLMER of Philadelphia expressed his pleasure that Dr. Thomas had found the arsenobenzol prepared in the Dermatological Research Laboratories of the Philadelphia Polyclinic of low toxicity, which observation was in accord with those of many physicians throughout the country. This arsenobenzol, he explained, was submitted to severe animal tests, in amounts equivalent to 3.6 grams per 60 kilograms, or about 125 lb. of body weight. Experimental and clinical data indicated the superior spirocheticidal activity of salvarsan and arsenobenzol over neosalvarsan. In an experimental study of the toxicity of various mercurials he had found that insoluble salts of mercury as the salicylates were very slowly absorbed from the subcutaneous and muscular tissues. For this reason physicians should avoid administering such preparations at close intervals. He believed the particularly favorable results reported by Dr. Thomas upon the treatment of syphilis as judged by the effects upon the Wassermann reaction to be due to the technic employed in the Wassermann reaction and more particularly the employment of an alcoholic extract of syphilitic liver as antigen. These results were not in accord with his own experience and that of many others. A study of antigens since 1912 and covering over 3000 tests with a number of different antigens Dr. Kolmer said had shown conclusively the superiority of cholesternized extracts as antigens in this reaction. He believed it a serious error to discontinue treatment on the basis of a negative test with an antigen of alcoholic syphilitic liver. Experience had taught him that a number of such patients were still Wassermann positive and could be rendered Wassermann negative with additional treatment. The Hecht-Gradwohl reaction as a control on the Wassermann had been found by him to yield about 12 per cent. more true positive reactions than the Wassermann. He regarded the Hech-Gradwohl reaction as the best serological evidence of the cure of syphilis with which he was familiar, and believed that no case of syphilis should be discharged from observation until the Wassermann reaction was negative with cholesternized antigens and then negative in the Hecht-Gradwohl reaction.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held May 11, 1916.

DR. ROYAL S. HAYNES IN THE CHAIR.

Report of a Case of Chondrodystrophy (from the Vanderbilt Clinic).—Dr. JESSE F. SAMMIS presented this report. He stated that the patient was a child, 9 months of age, whose chief complaint was inability to hold up the head. This child was the youngest of four children, the others being perfectly normal in both physical and mental development. The family history was negative. The child was born at 8¾ months intrauterine life, its weight at birth being given as 12 pounds. The labor was difficult and the child extremely cyanotic, having been resuscitated with difficulty. The child had been normal until four months of age, when it was noticed that the head appeared to be increasing in size very rapidly and that the child was making no effort to sit up. At nine months of age the child could hold up his head but could not sit up. He played and laughed in a normal way and appeared almost as happy as other children of his age. He was presented because he exhibited all the characteristics of achondroplasia in a typical way. The disproportion between the trunk and the extremities was marked, the hands scarcely reaching to the waist line; the skin, owing to the shortness of the extremities, hung in folds. There was the prominent forehead, the saddle nose, and the protruding jaw characteristic of this condition. The abdomen was prominent and an umbilical hernia was present. There was a slight lateral curvature of the spine and kyphosis. The hands were of the type described as "trident." There was considerable relaxation of the ligaments and the child's muscular development was poor. The liver and the spleen were both easily palpable. The Wassermann was negative. The measurements showed the great disproportion between the head, the limbs, and the trunk characteristic of chondrodystrophy.

Autoserum Treatment of Chorea.—Dr. ABRAHAM GOODMAN presented this communication. He first reviewed the literature of chorea, especially with reference to etiological investigations. He said his attention was first attracted to the subject by two cases admitted to the German Hospital with a diagnosis of chorea. In one of these cases the choreic movements were augmented to a high degree in a short time and the child developed an intense coma. It was suspected they were dealing with a miliary tuberculosis of the central nervous system. All the usual forms of medication were tried without avail. It had occurred to the writer, in 1913, that if one could use the serum of a patient with chorea and inject it into the spinal column favorable results might be obtained; that possibly the enzymes or the protein bodies might be a factor in the disease. Realizing the dangers of such a procedure, they made cultures of the blood and spinal fluid of choreic patients and in none could they demonstrate any organism. The use of salvarsanized serum had in the meantime given additional encouragement to work along these lines, so they determined to try it. The first case was the one described above. They felt that they would lose the case and that the use of the serum was justified. They employed this method and the child became quiet within two days. One should be sure he was dealing with a case of chorea before applying this treatment, since every case with choreiform movements was not a case of true chorea. Another important factor in the treatment of cases of chorea with autoserum was to be sure that all drug medication was eliminated. To be sure that any treatment in chorea was effective it must give quick results; if it was slow in producing an effect one could not be sure that the disease was not self-limited. With the autoserum the effect was manifested within two or three days. The method employed was briefly as follows: The child was allowed to lie in the ward for three or four days and in the meantime other infections, as syphilis, were excluded. They then drew off 45 or 50 c.c. of blood and centrifuged it. The serum was then pipetted off and kept for two hours at room temperature. A lumbar puncture was then done and 20 c.c. of the spinal fluid withdrawn. The serum was then taken from the incubator and very slowly injected into the spinal cord, allowing ten or fifteen minutes to inject 15 c.c. It was very important that the injection be made slowly so as not to disturb the equilibrium. The patient was then put to bed and there was no immediate reaction. At times there might be a rise in temperature, but this was exceptional. Dr. Goodman said they had thus far made from 20 to 25 such injections without any serious results. It was amazing to see how quickly these cases of chorea responded to this treatment. Dr. Smith had a case at the Vanderbilt Clinic that had been growing worse for three months. The child exhibited most violent movements and after two injections was cured and discharged. At the present time they were engaged in trying to find wherein the actual value of this procedure lay, whether it was due to an antibody, an enzyme, a protein, or what not. In the meantime any remedy that would relieve this distressing malady was worthy of careful consideration.

Dr. SAMUEL FELDSTEIN of Brooklyn said that at the Brooklyn Jewish Hospital they had recently treated a case of chorea by Dr. Goodman's method with most amazing results. This patient was a girl, 13 years of age, who two months previously had begun to suffer from rheumatic polyarthritis which necessitated her stay in bed for three weeks. After ten days' relief she was again compelled to take to her bed on account of the recurrence of the articular symptoms. Three days previous to her admission she was seized with severe choreic movements, these being so violent at the time of admission that a thorough physical examination could not be made. Her temperature was 100.4° F., pulse 120, and respirations 26. There were signs of a mitral regurgitation. After observing the patient for three days and being compelled to give dionin in ⅛ grain doses at night for the extreme restlessness, the child's condition became aggravated. They then removed 40 c.c. of blood from an arm vein and kept it at room temperature, allowing the serum to separate spontaneously. Most of the serum was clear, the remainder was centrifuged. They then removed 20 c.c. of clear fluid from the spinal canal and injected 10 c.c. of the serum. Following the injection there was considerable reaction, rise in temperature to 102° F., headache, and rigidity of the neck. These symptoms disappeared the following day. The day after the choreic movements were greatly decreased, and by the third day had largely disappeared. A week later the injection was repeated, this time allowing the serum to separate spontaneously at room temperature over night. The second treatment was followed by a much milder reaction. A few days later the patient was practically free from spontaneous choreic movements, and had remained so up to the present time.

Dr. CHARLES H. SMITH said he had seen the case of chorea to which Dr. Goodman had referred and that if he had cured that case he had performed a miracle, for it was the most severe case of chorea he had ever seen. Every attempt had been made to alleviate the condition of that child. It had received maximum doses of salicylates, bromides, chloral, arsenic, and tonics, and it scarcely seemed possible that it could be cured.

Dr. RUDOLPH MOFFETT said he had been associated with Dr. Goodman at the German Hospital and had observed this treatment, and he could only say that it worked wonderfully. After injecting a case it cleared up within a few days. They had been using 10 c.c. in making the injections, and he thought they should use 15 c.c. and that they might thus avoid the necessity of giving a second injection.

Observations on Tuberculosis at the Vanderbilt Clinic.—Drs. CHARLES H. SMITH and H. LAMBERT BIBBY presented this contribution, which was read by Dr. Smith. He said that when a child was brought to them for examination there were two questions which they always asked: (*a*) "Has the child been infected with tuberculosis?" This question was answered by the skin test. (*b*) "Is the infection latent or active?" The terms latent and active were preferable to infection and disease, since they were more accurate and since all infection meant disease. An active tuberculosis in a child was not like incipient tuberculosis in the adult. In the child the lesion was not apical, often not pulmonary, but by node or hilus infiltration. This made the diagnosis extremely difficult and quite different from making a diagnosis in the adult. The diagnosis in the child was made on symptoms of impaired nutrition and anemia, undersize, and failure to gain in weight at the proper rate. The presence of an irregular fever lasting over a considerable length of time was very suggestive. Other symptoms that were valuable were anorexia, fatigue, languor, headache, and night sweats. In some instances the fever seemed to incite

the child to unusual activity. In children cough and positive chest signs were rare, but there might be transient bronchitis, asthmatic bronchitis, or enlarged bronchial lymph nodes. A latent tuberculosis was shown by a positive von Pirquet test and no symptoms or signs of the disease. The frequency of these various symptoms in a series of 80 cases giving a positive von Pirquet reaction were as follows: Fever in 16 cases; no gain in weight in 9; loss of weight in 7; failure to gain when at rest in 3. Among these 80 cases, 21 or 25 per cent. had tuberculosis in the active stage and all were without the signs of the disease. With reference to the von Pirquet test there were several points to be observed. It was better to perform the test with a scarifier as one was less likely to draw blood in this way. The skin should be properly sterilized before making the inoculation and should be allowed to dry before the dressing was applied. A protective dressing should be applied to protect the puncture from contamination from clothing or finger nails. They had found physical signs in the lungs in only 21 out of 150 cases, and these consisted in slight changes in the breath sounds. Dullness was difficult to detect and uncertain. The physical signs detected in these 21 cases were transient localized râles at the apex with a positive von Pirquet in one case, localized râles in the axilla in three cases, two with a negative and one with a positive von Pirquet; general bronchitis (accidental) in two cases, one giving a positive and one a negative von Pirquet, asthmatic bronchitis in five cases, all positive; pleurisy in four cases, all positive; consolidation with cavity formation in four cases, three giving a positive and one a negative von Pirquet reaction, and two cases with pertussis. This gave 14 per cent. in 150 cases in whom there was a probability of tuberculosis; the larger number of these gave a positive von Pirquet reaction but some gave a negative reaction. The signs of involvement of the bronchial lymph nodes were dullness, tender spines, and Despine's sign. Enlarged bronchial lymph nodes and infiltration of the hilus caused an increased conductivity of the sounds, but this sign was not pathognomonic. There was some confusion as to just what was meant by Despine's sign and it was better to say whispered bronchophony to a given vertebra than to say Despine's sign positive. There were certain points to be observed in eliciting Despine's sign. The room must be quiet; the sign could not be elicited where persons were walking about and talking. The child must be able to whisper well; it was, of course, impossible to get the cooperation of a child under the age of three or four years. It was well to listen high in the cervical and low in the dorsal region and then to continue to listen above and below until the point was reached at which one heard the vesicular sound. This point varied considerably in different subjects. The *x*-ray, in making a diagnosis, was either a brilliant aid or a great disappointment. In order to get information one must get a good *x*-ray with a short exposure. When there was a positive tuberculous infection, the *x*-ray might show enlarged bronchial nodes, or tracheobronchial involvement by large central shadows, or small nodes might be shown along the main bronchi. Small dark shadows well separated from the root shadows were very suspicious. Pleural thickenings might be noted which were interlobar or from old pleural effusions or infiltrations. There might be a fibrosis extending out from the hilus region, but it must be remembered that there were variations in the hilus shadows normally present. The *x*-ray might show consolidation or cavities, but it had been found that the cavities were much smaller than the signs would indicate. In regard to treatment, it might be said that children with latent tuberculosis needed watchful care, extra rest, air, and food. Children with symptoms of active disease should be put to bed in the open air with careful feeding and kept in bed until the temperature became normal. They must be watched for months and years in order to detect any signs of relapse. At the present time there were insufficient preventoria and sanatoria. All children with positive von Pirquet reactions needed careful watching; if such a child ran a temperature it should be considered as needing the same care and treatment as an active case of tuberculosis. At the present time our sanatoria took only children from homes in which there were members with tuberculosis, but made no provision for the child accidentally infected from some other source.

Dr. Franklin Morris Class said he agreed with everything that Dr. Smith had said. He saw many of his patients at the Vanderbilt Clinic Day Camp and saw what he had accomplished. The most difficult cases to diagnose were the early cases of tuberculosis in children under twelve years of age. He was also convinced that most children suffering from early tuberculosis showed no signs in the lungs; and those cases showing pulmonary signs generally suffered from an infection other than tuberculosis. It was especially difficult to make a diagnosis in a dispensary as one had to see each case over a considerable period of time.

Dr. Leon T. LeWald said the problem of making a diagnosis of early tuberculosis in children was just as hard for the roentgenologist as for one who based his diagnosis on physical signs. There might be a small focus in a bronchial gland which the *x*-ray did not readily show. As to Despine's sign, there was considerable variation in the vertebræ and that explained the difficulty in the location of the sounds. It was also difficult to determine the presence of a small focus as the shadow of the cross section of a bronchus might be mistaken for an enlarged gland. It was advisable to have stereoscopic radiographs not only in one plane, but taken at different angles, at right angles, and at oblique angles.

Dr. Maurice Fishberg said that an important point had been omitted in the discussion of the Despine's sign. In interpreting the findings in tracheophony we must bear in mind certain anatomical peculiarities of the bifurcation of the trachea, mainly according to the age of the patient. In infants under three years of age the bifurcation was on a level with the seventh cervical vertebral spine, but with advancing age it sank lower and lower. At the age of eight years it was on a level with the third dorsal vertebral spine, and at twelve years of age it was as low as the fourth dorsal spine. In adults it might be as low as the fifth or even the sixth dorsal vertebral spine. Under the circumstances the sign was positive in a child under three years when tracheophony was heard lower than the first dorsal vertebra; in a child of six the sign was negative when tracheophony was audible above the third spine. In a child of twelve tracheophony might be audible as low as the fourth or fifth dorsal spine without enlarged thoracic glands. In many children this sign was negative though the glands were enlarged because the trachea was situated more anteriorly than normally, or only the anterior glands were tuberculous. After all the sign was due to the interposition of anything between the trachea and the spine, and tuberculous glands were the most common in childhood. In adults we might find tracheophony on rare occasions as low as the lumbar vertebræ with or without being able to assign a plausible cause to the phenomena. In children if these anatomical points were not borne in mind the sign was of little value.

Dr. L. Emmett Holt said that, with regard to the von Pirquet reaction in tuberculous meningitis, he thought the impression had gained currency that it was only exceptionally that one got a positive von Pirquet reaction in that disease. It had been their experience that except in the last stages of the disease, when the patient was extremely prostrated, the skin test had almost always been positive. At other times a negative test might be of great value. This was illustrated in the case of a child who was admitted to the hospital because the mother had noticed a lump on the head. This proved to be a bulging fontanelle. There was a history of convulsions, fever, and drowsiness. A lumbar puncture was done and 120 c.c. of perfectly clear normal fluid withdrawn. In this instance the von Pirquet test was negative and the child recovered. The symptoms in this case pointed to tuberculous meningitis but the child certainly did not have that disease. It probably belonged to that type of meningitis sometimes called serous meningitis. As to Despine's sign, Dr. Holt said he had been impressed by the extreme variability of the sign in different children. He did not believe it was possible to fix on any one point and say that this was the exact point at which the whispered voice was significant. It was a valuable sign for diagnosis and was usually best obtained on the right side. Early wasting was often absent with active tuberculosis in infancy. One might see a child with fairly positive signs of tuberculosis and yet the child would show no loss of weight for a considerable time, and a child might have a fairly active tuberculosis and even gain weight. Loss of weight in young children was not so significant of tuberculosis as in older ones. Most of the children with tuberculous meningitis were rosy and plump up to the time when active symptoms of meningitis developed.

Dr. ABRAHAM L. GOODMAN said that one point that had impressed him was the difference in tuberculosis in the very young children and those betwen the ages of ten and twelve years. He had ben amazed to see how well nourished these young children were, and how extensive the tuberculosis often was without any particular objective sign. In older children these objective signs were usually present. Most of these younger children had enlarged bronchial lymph nodes and the von Pirquet reaction was usually positive. These cases of early tuberculosis exhibited indefinite fevers accompanied by gastrointestinal disturbances, and were treated often as such until the condition was recognized. Every case of indefinite fever in early life should be looked upon as a possible tuberculosis and, with the added refinement in technique and execution in detail of *x*-ray examination, the early appreciation of tuberculosis was made possible. When one found enlarged mediastinal glands together with a von Pirquet reaction and an increased temperature from time to time, one was justified in making a diagnosis of incipient tuberculosis. When such children were placed under proper hygienic and sanitary conditions and given daily doses of guiacol and arsenic for years, they could be permanently cured. Guiacol and arsenic not only had a favorable influence on tuberculous processes in the lungs but had a direct influence in the process of metabolism.

Dr. CHARLES H. SMITH, in closing the discussion, said that with reference to Despine's sign, it was difficult to get a child under two years of age to whisper; one could not usually get a child under three or four years of age to whisper properly. By the time a child was three or four years of age the bifurcation of the trachea was approximately as far down as at the age of twelve years. There must be some significance in this sign as one gets it as low as the fourth or sixth dorsal vertebra and, on the other hand, there were a large number of cases in which it stopped at the first dorsal or seventh cervical vertebra. Undoubtedly it did occur without the presence of tuberculosis, but the figures with reference to its occurrence were certainly suggestive.

"The Most Notorious of All Medical Practitioners."—Marat is notorious not for charlatanism—for, as a matter of fact, he was never accused of quackery—but because he was one of the moving spirits of the French Revolution. Until quite recently laymen and most physicians seem not to have realized that he was, for his time, a distinguished scientist and physician. But his entire life was a series of paradoxes. He was racially Italian, not French, and his true name was Mara. He was born and raised in Switzerland. He became so good a Britisher that he practised in London for ten or twelve years, was received in its best literary and scientific circles, and published in English many articles on physics. He received a medical degree from St. Andrews. His political and iconoclastic career was also begun in England when he wrote "The Chains of Slavery," in 1774. During his sojourn in London he wrote three pamphlets on medical subjects, two of which were devoted to affections of the eye. About 1777 he removed to France, and wrote works in French, but not until 1788 did he begin to show activity as a revolutionist. His political career, which lasted a bare five years up to his assassination, was so momentous that it completely obscured his earlier activities. His health suffered, chiefly as the results of an irritating dermatosis which caused constant unrest and insomnia. It is not impossible that this distressing disease may have had much to do with his apparently murderous mania which kept the guillotine working overtime.—C. Edward Wallis, in the Proceedings of the Royal Society of Medicine.

The Ambulance Driver.—An American ambulance driver, a Harvard student, has contributed to the October number of the *American Red Cross Magazine* a thrilling account of ten days' experiences before Verdun, immediately preceding the Somme engagements. He tells a story of the rescue of wounded soldiers on the French side, in the midst of terrific shrapnel and gas fighting, so graphically that an editorial note says it "exceeds in vividness and action anything bearing on individual achievement that has come to our hands from the Western war front in Europe." This heroic young American, a member of the Harvard section which was later honored with military medals and crosses of war, "rolled" for ten nights in his light auto ambulance bringing to field hospitals badly wounded "blessés." He describes plunging into gas clouds, wearing a gas mask, with shrapnel shells whistling and exploding about his car, and of rescuing at one time one of his fellow ambulance men, the whole back of whose car had been shot away. This man he found in a pitiful plight, his nerves gone, and unable to talk straight. With his car full of wounded men, and shells exploding all about one of the rear wheels, his ambulance became entangled in barbed wire. His frantic efforts to unwind this wire, now and then ducking under his car because of the warning whistle of a shell, are so realistically described that the reader might easily imagine being at his side. The explosion of one shell threw him on his face in a pool of horse's gore, and another shell blew out both of the rear tires of his car so that one trip back was made on the rims over a road literally paved with dead horses and men and wreckage.

THE MANAGEMENT OF POLIOMYELITIS, WITH A VIEW TO MINIMIZING THE ULTIMATE DISABILITY.*

BY ROBERT W. LOVETT, M.D.,

BOSTON.

IT occasionally happens that in the treatment of a certain disease we allow ourselves too largely to be governed by generally accepted ideas and sometimes tradition too greatly influences us. Such a state of affairs does not make for progress and chiefly pertains to those affections which are not forced upon our attention by some undue prevalence.

Sometimes a more careful study of fundamental facts with regard to such diseases changes our point of view and gives us greater efficiency in our study of their phenomena and in our therapeutics.

It is to such a consideration of poliomyelitis that I would invite your attention in the present paper. I have no startling facts to bring forward, no new discovery, no revolutionary therapeutic measures, but it seems to me that the data already at our command are sufficient to warrant a renewed study of them, to see if in them we cannot find encouragement for greater hopefulness in our outlook and for greater efficiency in our treatment. The situation surely warrants an attempt in this direction, for you have in New York City to-day several thousand children paralyzed in the last few months and in the rest of the country several thousand others, and the problem of treating these children in the best possible way is not only a surgical and humanitarian problem of great present interest and importance, but an economic question of no mean dimensions. It is particularly incumbent, moreover, on those of us who are concerned with the therapeutic side of medicine to remember that the best brains in the country have been organized for the study of the epidemiology and pathology of this disease and are taking their task most seriously. Although theirs is the more important work because prevention is better than cure, it is none the less imperative for us clinicians to take our problem just as seriously and to inquire into the efficacy of our present methods and the possibility of improving them. Until the happy day arrives when this disease may be controlled or prevented, it is our business to see that the wreckage which is left behind these epidemics is efficiently and economically cared for.

Poliomyelitis in its paralytic form has been too much regarded as a chronic condition of no great interest except in its operative aspect, hopeless in general so far as restoration of function goes, although recoveries are occasionally seen, but on the whole a disabling condition best met by braces to make walking possible and in the later stages often to be helped by operations. We orthopedic surgeons have largely prescribed braces with perhaps massage or electricity or muscle training as probably of use and have been much interested in the operative question. The neurologists have been less enthusiastic about braces, but have on the whole favored electricity, about the value of which there has been much controversy. The general practitioner has often ordered braces from the instrument maker, who has a free hand in their design and fitting and has felt that electricity and massage were of use, and all have on the whole regarded the affection as an undesirable one to treat and a tiresome thing to have anything to do with except in its operative aspect.

The point of view which I shall advocate in this paper is that the treatment of poliomyelitis is one of the most gratifying and satisfactory problems in surgery, for the reason that nowhere does the close analysis of each case and the application to it of commonly accepted anatomical and physiological principles yield more satisfactory results, that the problem in every case after the acute attack is a problem in functional anatomy exact, clean cut, and clear, that the final functional results are in most cases largely influenced by the precision, efficiency and persistence of the treatment, especially in the early stages, and that certain phenomena of the disease, clinical and pathological, warrant us in holding out to these patients a much higher degree of hopefulness than we have been in the habit of doing. I am fully aware that such a statement requires very decided substantiation and such substantiation I hope to present to you in the form of figures, hitherto unpublished, later on in the paper. But for the moment I will ask you to join with me in laying aside preconceived ideas about braces, to omit for the time being controversial matters about electricity, to postpone for a few minutes the discussion of operative measures and to consider first what the clinical pathology of the disease really is and what anatomical and physiological measures based on general principles may most reasonably be expected to be of therapeutic value.

Anterior poliomyelitis is to be regarded as an infectious disease accompanied in a certain proportion of cases by paralysis. Paralysis is not essential, but accidental, and the proportion of cases in which it does or does not occur is at present undetermined, but most of the men who have most carefully studied the epidemiology of the disease believe that the so-called abortive or non-paralytic form is very common, possibly more common than the paralytic form. From the standpoint of public health and of therapeutics this point of view of the disease is obviously much sounder than to regard it as a paralytic affection often occurring without pa-

*Read at a meeting of the New York Academy of Medicine, October 5, 1916.

ralysis. The paralysis is purely accidental and incidental, the infection is the central fact. In the present discussion, however, we are dealing wholly with the paralytic form of the disease.

The infectious agent, which is the cause of the affection, having entered the system, shows a particular affinity for the cerebrospinal axis on which it inflicts special injury, greatest in the spinal cord, but only to a less extent in the brain. The significant pathological changes in the cord are a perivascular infiltration of the vessels supplying the gray matter, edema, punctate or larger hemorrhages in the anterior horns, degeneration or necrosis of the nerve centers, and a widely distributed meningitis. Commensurate changes also occur in the medulla and brain. The posterior nerve root ganglion is also involved in the process, and in experimental pathology is the first of the structures to show changes. The clinical expression of these processes is a widely distributed and erratic motor impairment, accompanied in most cases at the outset by marked tenderness over the affected area. The cause of this motor impairment is to be attributed to one or more of the following pathological conditions which exist.

1. A mechanical anemia of the motor cells in the affected areas of the cord results from the obstruction of the vessels from the perivascular infiltration. Such cells may recover or go on to necrosis, depending on the extent and duration of the obstruction. If the effusion is soon absorbed, the blood returns to the cell and it resumes function.

2. The edema of the affected part of the cord, which is a prominent but temporary feature, interferes with motor function in the edematous area.

3. The hemorrhages, if in the neighborhood of motor cells, may abolish their function.

4. There is perhaps a direct toxic action of the virus on the motor cells, causing their destruction.

If the patient lives, the perivascular infiltration and edema subside gradually or quickly and the hemorrhagic products are absorbed, leaving behind the areas too much damaged to recover, which are converted into focal scleroses.

Such in the briefest outline is the process in its various stages that we are called on to treat. First an acute hemorrhagic myelitis, second a convalescent myelitis with returning power, and third a cord, in the motor area of which are scleroses, all stages accompanied by more or less motor impairment.

We surely cannot adopt or advocate any one treatment for all these stages and we must clearly distinguish between the different phases of the process in considering therapeutics.

Three phases of the clinical phenomena suggest three pathological stages. These are:

1. *The Stage of Onset.*—Pathologically it is an acute hemorrhagic myelitis and meningitis, and clinically the child is suffering from that and from a severe infection. It covers the period from the beginning of the illness until the disappearance of the tenderness, because tenderness must be accepted as evidence of an active process still existent in the cord. In those exceptional cases where tenderness is absent, this stage may be counted as lasting from four to six weeks.

2. *The Stage of Convalescence.*—Pathologically, the products of the hemorrhage are being absorbed, edema and perivascular infiltration are diminishing, and physiologically the motor area of the brain is trying to send impulses to the affected muscles to find their path partly or wholly blocked. Clinically, the child is more active and trying to use the affected member, tenderness has gone, but the power to execute certain movements is impaired or lost. But there is a continual gain and under all conditions of treatment or neglect, improvement occurs, for a while. So-called trophic disturbances begin to appear, circulation is impaired, affected members are atrophied and do not grow as they should and deformities begin to develop. This stage begins with the disappearance of tenderness and lasts for about two years.

3. *The Chronic Stage.*—Pathologically edema and perivascular infiltration have long since disappeared, the meningitis has healed, and in place of the destroyed areas in the cord are found focal glioses (focal scleroses due to increase of neuroglia tissue). These lesions are analagous to focal scleroses, such as fibroses or areas of scar tissue due to increase of connective tissue in other organs.

Clinically the case is apparently stationary, or retrograding. Spontaneous improvement is much less noticeable than in the previous stage and in many cases seems to have stopped. So-called trophic changes are present. Deformities from muscular contractions and gravity have occurred in many cases and further improvement without treatment is not to be hoped for. This stage apparently begins on the average about two years from the onset and continues through life.

I shall next ask you to consider for a moment certain general phenomena with regard to the disease which seem to have a definite bearing on the whole question of treatment before taking up the question of a definite plan of treatment for each of these phases.

We have been handicapped in our study of poliomyelitis in the past by the absence of any adequate quantitative method of examination. We have been in the position of an oculist who had no lenses at hand with which to examine his patients for errors in refraction, or of a physician who was obliged to treat typhoid fever without a thermometer. Now, although the latter, if an experienced man, might very probably carry the individual case through the attack perfectly well, his general study of the phenomena of typhoid fever would be of no great value to himself or to others, because he would have no more exact quantitative instrument than his hand. We have been in exactly this position with regard to poliomyelitis and our knowledge of the various phenomena of the disease has been for this reason necessarily inaccurate and on the whole loose.

In January, 1915, I was asked by the State Board of Health of Vermont to undertake the treatment of the cases of poliomyelitis occurring in that state in the epidemic of 1914, and pursued the work in connection with laboratory work under the charge of the Rockefeller Institute. It became perfectly evident on examining cases in large numbers that without some quantitative standard, no reliable study of the group could be made nor would it be possible to present anything but impressions as to the result of treatment. The problem was therefore presented to the Physiological Department of Harvard University, and Professors Cannon and Martin were good enough to take the matter up, and by June Professor Martin had a method far enough advanced for preliminary trial in Boston at the Children's Hospital, and it has since then been used in Vermont in all of our clinics.

The conclusions that I shall present rest on obser-

vations on about 15,000 muscular groups.* The method has been already described in detail and consists in ascertaining the strength of twenty-two different muscle groups on each side of the body in their resistance to the pull of a spring balance. The method has proved reliable and has verified itself.

Under these conditions it is obvious that a much more accurate study of the phenomena presented by affected muscles was possible than before, and the conclusions which I shall next present are the outcome of that quantitative study.

1. *Partial Paralysis is Much More Common than Total.*—The original manual examination of individual muscles in the Vermont series showed that in 1452 muscles recorded, partial paralysis was two and one-half times as common as total paralysis. The spring balance muscle test subsequently used in 1069 muscular groups in the Vermont series showed partial paralysis to be nine times as common as total. This greater proportion was because of the greater delicacy of the test over the hand examination which placed in the partly paralyzed class many subnormal muscles which by the hand would have been classed as normal. The practical outcome is that partial paralysis is very much more common than total.

Total paralysis, when present, in 82 per cent. of 196 cases existed below the knee. These data must necessarily modify somewhat our conception of poliomyelitis and its treatment. We are not dealing with a total and hopeless loss of power except in a small percentage of the muscles, but with a weakening which is of various grades. Now the treatment of weakened muscles rather than the treatment of totally paralyzed muscles comes at once to the front as our main problem in poliomyelitis. It, therefore, should be our aim to conserve and stimulate and improve by every means in our power such weakened muscles with a view of bringing them as near to normal as may be. It is very important to a patient who has, *e.g.* lost 80 per cent. of his gastrocnemius power whether that muscle gains 10 or 50 per cent. of that loss.

It is obvious that the conservation of muscular strength and the utmost care for the affected muscles should be our chief end in treatment. Certain factors bear on this matter of how we may best handle the muscles with a view of securing the maximum improvement.

Spontaneous Improvement.—A factor of much importance in this matter of securing muscular improvement lies in the existence of spontaneous improvement which starts as soon as the tenderness has disappeared. The Vermont observations have shown that this goes on much longer than has been generally believed. In a series of cases one year after the attack, measured at an interval of two months, muscles which were not treated but which had been affected, showed an improvement ratio of 2 to 1 which must be put down to spontaneous improvement. Of 44 totally paralyzed muscles in 7 cases affected over a year, 27 per cent. developed demonstrable power without treatment in a two months interval.

We have then in our aim to improve the condition of muscles the fact that spontaneous improvement even in badly affected muscles exists to a considerable degree at periods later than usually stated.

Fatigue and Its Effect.—The overuse of convalescent affected muscles and the over-treatment of such muscles by too much massage and too much therapeutic muscular exercise is undeniably bad and is being generally so regarded. It is a fact recognized by the present advocacy of prolonged recumbency after the acute attack is over and the danger of overuse is wholly borne out by the Vermont muscle test figures. Not only does overuse delay favorable progress, but undoubtedly can lead to muscular deterioration and may destroy apparently permanently the returning power in convalescent muscles. Consequently the worst possible advice that can be given to parents is to encourage patients to be as active as they can to "strengthen" the muscles.

The reason for all this is that the loss of power in affected muscles in the first months of the disease is a considerable one, leaving the muscle as a rule with a degree of power quite too little to enable it to come anywhere near performing its normal function. Very little activity, therefore, may be enough to constitute gross overuse of the neuromuscular mechanism, and such overuse is admittedly detrimental to any muscle, normal or abnormal. Consequently, while we feel that we are safeguarding the patient by restricting activity we may still be overtaxing him. One must therefore remember that the danger of over-exercising convalescent muscles is very much greater than the danger of under-exercising them.

Three salient facts, therefore, stand out from the study of the Vermont and other cases by means of a quantitative test. These are: (1) Partial paralysis is more common than total. (2) Spontaneous improvement goes on a long time. (3) Fatigue and over-exercise, therapeutic or otherwise, are dangerous.

We are now in a position to return to the question of what should consitute the treatment of each of the three phases of the disease already defined, in the light of the pathology of each stage and in view of these general and more or less fundamental considerations.

1. *Treatment of the Acute Phase.* (From the onset to the disappearance of tenderness.)—In this stage Nature is attempting to repair the damage done to the cord, especially to the motor area. Rest and absence of irritation and of meddlesome therapeutics should constitute our treatment at this stage. There is no evidence that drugs are of any use, nor would one reasonably expect much from counter-irritation, externally applied applications of heat or cold, or from electricity.

It is not physiological to irritate and stimulate the peripheral ends of nerves connected with affected and hemorrhagic nerve centers by massage and muscular exercise while the acute process, as evidenced by tenderness, exists. Joints will not become ankylosed, muscles will not hopelessly atrophy, and the patient will not become bedridden because he is kept quiet for as long a time as need be to enable the damaged cord to repair without interference. Deformities may occur in two or three weeks after the onset and must be prevented by support of the feet at a right angle (where the most common early deformity appears) by plaster of Paris splints or some similar simple contrivance. This policy of doing nothing is trying to the parents who have heard of the wonders of massage and of electricity and are anxious that no time should be lost and trying also even to the experienced surgeon when the tenderness is of unduly long duration. There is evidence to show that hexamethylenamin prevents or delays the infection in monkeys, but no evidence

* Lovett & Martin. *American Journal of Orthopedic Surgery*, July, 1916.

to show that it is of use after the infection has occurred. Immersion in a warm saline bath is agreeable and apparently beneficial toward the end of this stage and may be comfortably carried out by immersing the patient on a sheet. There is a reason to hope that the administration intraspinously of the blood serum of recovered patients as early as possible in the onset of the disease is a therapeutic measure of value in diminishing mortality and limiting the paralysis.

The treatment of the acute stage may be summarized as follows: Rest, the avoidance of meddlesome therapeutics, the prevention of deformities, and probably the early administration of the blood serum of immune patients.

Treatment of the Convalescent Phase.—During this period one faces squarely the question of muscular care and development. The destructive process has ceased, the harm has been done, the development of the possibilities of what remains is our problem. I believe that in this stage the amount of ultimate function is largely determined and we must remember that nature is assisting us to the best of her ability with the great asset of spontaneous improvement which is more marked in the first six months than in the second six, and more marked in the second six than in the last six months of the two-year period arbitrarily allotted to this stage.

Perhaps certain data with regard to the gastrocnemius muscle may make clear what seems to me to be the general behavior of muscles during this time. The calf muscle should normally be able to exert a force in pounds of from two to three times the body weight of the individual. This muscle is very frequently weakened by poliomyelitis. If it is partially paralyzed and is immediately protected by a high heel when the upright position is assumed, this throws it out of use in walking. If walking is restricted and if the muscle is judiciously exercised, in all cases that I have observed it has gained in muscular strength, and in two cases it has been quantitatively recorded as returning to the normal amount of power within two years. If it is not so protected and exercised, it has in all cases which I have observed lost power and stretched, with the acquirement of a calcaneus deformity of greater or less degree; whether it goes on to a complete loss of power cannot yet be said, because the quantitative observations on which these statements rest have not yet covered a sufficiently long period. But what happens to the gastrocnemius muscle which is easily measured and checked and observed, undoubtedly points to a general rule governing the behavior of other muscles not so easily observed and measured. So that in formulating the treatment for this stage the different reaction of this one muscle to protection and to over-fatigue may be borne in mind as probably typical.

With regard to the specific treatment of this phase, when the tenderness has wholly disappeared, or at the end of six weeks or therabouts in cases where there has been no tenderness, the question arises whether we shall begin to get the patient up or whether we shall continue recumbency, and here there is ground for a perfectly reasonable difference of opinion, probably soon to be settled here in New York City by your immense experience in the present epidemic.

Those who would keep the patient recumbent for months argue that in that way they avoid fatiguing the convalescent muscles, that the damaged nerve centers have ample time given them for complete recovery, and that muscle training and massage can be carried on perfectly well while the patient is in bed, all of which is perfectly true.

My own experience has led me, however, to feel that soon after the acute stage is over it is on the whole better to get the patient on his feet; that is, in about two or three months after the attack. The prolonged recumbency is not favorable to the circulation, which is intended to work at least some of the time in the upright position. The nervous system of children is not desirably affected by such prolonged confinement, and what is more important is that when the patient is put on his feet there is an instictive effort to balance and hold himself upright, which exercises muscles not otherwise to be reached. But this ambulatory treatment must meet the objection that fatigue may be incurred by an attempt to get about, which is perfectly true, and this must be guarded against. If the people are not intelligent enough to follow directions, prolonged recumbency would undoubtedly be the best treatment, provided, of course, that deformities were prevented. It has been too much the custom in the past to allow children to sit around for months and years with no treatment worthy of the name until they acquired the deformities of flexed hips, flexed knees and dropped feet, all favored by prolonged sitting. Still, although this danger exists, it is not a serious objection to the treatment by prolonged recumbency properly carried out. The only danger is that the unqualified advocacy of prolonged recumbency might seem to sanction a method which has been productive of great harm in the past in the hands of inexperienced persons.

With regard to the use of braces, corsets, and other forms of apparatus, it is necessary to define clearly what their place should be. Braces bear about the same relation to the treatment of poliomyelitis that crutches do to the treatment of fracture of the leg. They are compensatory rather than therapeutic. In a fracture of the leg there is a local injury which Nature is trying to repair. Now in order that the patient may get about we use a compensating appliance in the form of crutches, while locally we use ice bags, local fixation and massage at the different stages as our real treatment. If we are careless in our treatment, or in exceptional cases properly treated, we may get deformity or non-union, in which case we shall have to operate, otherwise we get complete cure. Now in poliomyelitis we have also an abnormal local process in the cerebrospinal axis which Nature is trying to repair. Unfortunately, this process cannot be as efficiently treated locally as can the fracture of the leg, nor does it spontaneously go on to a cure in nearly so large a number of cases as in fracture. But while it is progressing we use compensatory appliances in the form of braces to enable the patient to get about, while we attempt to hasten the repair of the local process by massage, muscle training, the avoidance of fatigue, and perhaps by electricity. Braces have, however, a further function in preventing muscular stretching and deformity, but then so do crutches in fractures, for if we allowed walking without crutches in imperfectly consolidated fractures we should get deformity and shortening. So if we regard braces as compensating and preventive appliances to be used in poliomyelitis rather than as therapeutic agencies we shall reach a more adequate idea of their proper place. To speak of the "brace treatment" of poliomyelitis would from this point of view be inaccurate.

The legitimate use of braces, however, is of great importance and its disadvantages and advantages must be carefully formulated.

Braces are heavy at best, and a weakened limb is not helped by carrying extra weight, the bands and lacings constrict the muscles, they induce an unnatural gait and prevent normal muscular action. On the other hand, they permit going about and many a patient would be practically bedridden without their use. They prevent muscular stretching and the loosening of joints, and most important of all they prevent or control deformity. The latter, if allowed to persist, at first affects the soft parts but later leads to serious bony distortion. Apparatus must be used in the majority of cases in poliomyelitis and much harm in the past has been done by trying to go without it. In what has been stated here I have in no way intended to criticise the legitimate use of braces, but simply to call attention to the fact that their chief value is compensatory and preventive rather than therapeutic, and that we must look elsewhere for our therapeutic aid. This consideration seems to me of primary importance.

With regard to the use of braces and apparatus, I find a very good rule as follows: If the patient cannot walk without such aid, or if in walking or standing he does so in a position of deformity, he should wear apparatus. It is essential that apparatus should be mechanically sound, light and properly fitted, for nowhere is nicety of adjustment so important in its direct effect on gait as in this disease. In the convalescent phase I believe that braces should be worn only for walking and then removed, and as in the first year very few children severely enough affected to require braces have any business to walk much on account of the danger of fatigue the braces will be worn but very little. If crutches are also necessary they should be used. Equilibrium must often be reckoned with by itself in children who have been long confined to bed, and such children must be taught to balance just as if they were learning to walk for the first time. This loss of balance is quite unrelated to the degree of paralysis present.

We will now assume that the patient is up, provided with braces if he needs them, and we must take up the most important question as to what we can do to improve the condition of the neuromuscular mechanism, bearing in mind the fact that most of the muscles are weakened and not totally paralyzed. There are three chief measures indicated, which are massage, electricity, and muscle training, the rationale of which must next be discussed, and in this matter we are approaching what I understand to be the real treatment of poliomyelitis at this stage.

Massage promotes the flow of blood and lymph from the affected limb and the displaced blood is replaced by a new supply and the circulation of the limb consequently stimulated. Waste products are removed and muscular atrophy and atony apparently delayed by it. But its effect is largely local, for it does not promote the passage of an impulse from the brain to muscle. Its overuse, either by too long treatments or too heavy manipulation is undoubtedly harmful and in the past has been responsible for more or less damage. A measure of undoubted use, we must not expect too much from it; there is nothing magical or mysterious about it and it can do harm as well as good.

Electricity.—This no place in which to enter into a controversial discussion of the value of electricity and I am only desirous of making what I believe to be a fair presentation of present opinion and to leave a definite statement to the time when I can back it up by quantitative figures on a sufficiently large number of cases with proper control over an adequate period of time. Such a series of observations has been provided for and will be soon taken up. "Impressions" resulting from the observation of the recovery rate of cases of poliomyelitis are unreliable, because the recovery rate of apparently similar cases varies enormously.

Faradic electricity is a mild form of exercise to muscles which will not contract voluntarily. It is disagreeable, but probably mildly effective under the conditions named.

Galvanic electricity and the newer forms, such as the high frequency, sinusoidal, static, Morton wave current, etc., are supposed to work in a way less definitely understood in increasing muscular power and improving nerve conductivity. In my own experience, where I have used electricity of one form or another on only one side of the bilateral cases, I have not been able to observe a faster gain on the side thus treated.

The objection to electrical treatment is that it has been extensively used, and for the most part in such a loose way that even its advocates would not expect much from its use, and that while this was being done the parents have as a rule neglected other measures, thinking that the patient was being adequately treated by the electricity alone.

My claim would be that until the case of electricity was definitely proved, it was better that it should not constitute the sole treatment and that electricity was probably of no value at all when carelessly applied by laymen.

That the use of electricity in connection with other therapeutic measures may or may not add to their efficiency, a matter which cannot be settled until quantitative examinations have been made in sufficient number.

Muscle training is the third of the therapeutic measures under consideration, and more closely than the other two meets the therapeutic requirements indicated by the pathology of this stage. In essence, it is an attempt to reconnect a cerebral motor impulse with a peripheral muscular contraction, a normal connection which has been impaired or lost by the injury to the motor centers in the cord occurring in the acute stage, so that cerebral motor impulses are checked or diminished at these impaired centers and the intended muscular contraction either occurs feebly or not at all. Now the method of muscle training aims at two things, first at forcing the efferent impulse to develop a new path around the disordered nerve center in the cord, and second to secure contraction of the desired muscle, however feeble, which is of course the best possible treatment of the muscle itself. These two attempts rest upon a sound anatomical and physiological basis. The motor nerve centers are grouped in cigar-shaped bundles running in the length of the cord and overlapping each other. Each muscle connects with more than one bundle and every bundle sends fibers to several muscles. Moreover, the intercommunication between the bundles is most extensive and intricate, consequently unless the destruction in the cord has been very extensive, the chance is that some new communicating path or some combination of paths can be established to carry a motor impulse of some

degree around the damaged area. If there is a railroad wreck blocking the main line, communication between terminals may be maintained by sending trains around the wreck by means of a branch track. So that there is no reason to believe that in muscles not totally paralyzed there is every prospect to expect continuous muscular improvement from repeated attempts to drive a motor impulse from brain to muscle, a permanent improvement in conductivity.

So far as the second aim, muscular development *per se*, is concerned, it is a matter of common information that muscular exercise in proper amounts strengthens muscles. The athletic trainer does not turn primarily to massage or electricity to strengthen weak muscles but to muscular exercise, which consists of active contractions. The muscles partially paralyzed in poliomyelitis are simply weakened muscles requiring an extremely small dose of exercise.

The practical application of muscle training is carried out by ordering the patient to execute a special movement and at the time of the effort assisting him manually to perform the movement.

Dorsal flexion of the foot, *e.g.* is performed with assistance for perhaps ten times, each time at the word of command with sufficient rest between the attempts to prevent fatigue.

The exercise and position suited to the especial muscle and its ability are selected.

Precision, care, and persistence are essential to success.

As a rule, intelligent parents can carry out muscle training by themselves with sufficient supervision to have the exercises changed as the muscles improve. Bringing the parents into the case, moreover, places the responsibility where it belongs, for the treatment to be successful must be carried on year after year to obtain the maximum results.

In six private cases, under muscle training at home, measured last winter, whose acute disease had been from three to nine years previous, with an average duration of six years, the average monthly percentage gain of strength in affected muscles was 8.2 per cent. These were the only cases of long duration in my private practice whose measurements were available. A woman with a weakened abductor muscle of one thigh and who wore a brace to correct a bad foot had never received other than brace treatment. The duration of the paralysis was thirty-six years. Under daily muscle training by an expert she gained 125 per cent in the strength of the gluteus medius muscle in six weeks. A patient in Vermont at the end of four years, who had had no previous treatment beyond braces, was started on home exercise in July, 1915. In two months his affected muscles had gained 470 per cent. in strength and his unaffected muscles 70 per cent., a net gain of 400 per cent. These muscles were severely affected. So that we may conclude that muscle training requires long continuation if the maximum results are to be obtained, and that it is effective at a later stage of the disease than generally supposed.

It is absolutely essential to success that muscle training should be preceded by a thorough and complete muscular examination. In brace treatment a thorough muscular examination would seem to be important, but paralysis or weakening of the abdominal muscles is constantly overlooked, lateral curvature of the spine in its early and curable stage is missed and local weakening in the arms is not looked for, as a rule, when the paralysis affects only the leg. The only safety lies in a complete examination of all the muscles which can be reached, whether they appear to be paralyzed or not. The Vermont measurements have shown the affection to be very widely distributed and that the affection of one muscle alone is rare. When one leg is affected, apparently alone, the other leg is as a rule somewhat involved, the more delicate our means of measurement the more widely distributed will be found the paralysis, an observation which brings the clinical phenomena of the affection more closely than before in accord with the modern pathological findings. For the most accurate type of work the spring balance muscle test is necessary, but it is complicated and requires practise on the part of two assistants, and great care in its use. For formulating the phenomena of the disease and analyzing the effect of treatment it is obviously essential, especially in connection with operative work.

As the problem in most cases is the problem of making the patient walk better, every patient who can walk should be made to do so and much will be seen in this way which otherwise would escape detection; lameness characteristic of certain muscles is shown in walking as in no other way. Children should walk naked and adults should wear trunks, bandages or union suits, as it is essential to have the whole body outline in view.

In entering here this plea for a thorough examination of every muscle in both arms, both legs, back and abdomen in every case, I am simply stating a perfectly obvious requirement for any really accurate treatment. In my own experience the results of the treatment are in large measure proportionate to the care, precision and persistence with which the treatment is given. Muscle training inaccurately formulated and carelessly carried out is of little therapeutic value.

Deformities as they occur in this stage should be removed. It is a sound rule that no non-operative treatment should be undertaken till fixed deformity has been removed. It is of no use to put braces on a child with flexion contraction of the hips, for he cannot walk with any facility, nor can a child with an equinus deformity (a dropped foot) use a brace properly.

The examination for deformity should go hand in hand with the muscular examination mentioned.

Deformity can generally be prevented, but if it is recognized only after it has occurred it should be treated as early as possible. The masures available are stretching, tenotomy, fasciotomy, myotomy, and rarely osteotomy. As this paper is intended to discuss principles and not details, this general statement about deformity must suffice.

The convalescent phase may now be summarized. It is the stage of muscular care and development. Braces may or may not be needed; if deformity occurs it should be removed. Of the three therapeutic measures available for muscular improvement, muscle training has the best physiological and anatomical basis. A thorough examination comprising every accessible muscle and a study of gait is obviously essential for proper treatment.

3. *The chronic stage* of poliomyelitis has in this paper been arbitrarily assumed as beginning two years after the onset, because it is only after this period by common consent that the operative question can be properly discussed. This has seemed to set a proper time for assuming the beginning of this stage. At this time the spontaneous improve-

ment is much less rapid than in earlier stages and the prospect of gain from the therapeutic measures described is less, but at no period of the disease can it be assumed that the possibility of improvement and sometimes of great improvement from the use of suitable therapeutic measures has ceased. Without treatment the patient is likely to remain stationary or to retrograde.

Braces may be still needed and are subject to the same rules as in the preceding stage, except that they may be worn continuously at this time with much less detriment than earlier in the disease. The danger of harm from fatigue still exists and must be guarded against if the best progress is to be made. What has been said of massage, electricity and muscle training still holds at this stage as in the former, except that improvement is less rapid. Deformity must be cleared up when it occurs or is found to be present.

In this stage first arises the important question of operative interference and the settlement of this question is in many cases the crucial feature of this stage. Operations are performed first to improve existing function and these are such operations as tendon transplantation and nerve transplantation, while the second class are done to secure better stability in badly paralyzed joints, and to this class belong artificial ankylosis, the use of silk ligaments, tendon fixation and the removal of the astragalus with backward displacement of the foot. Experience has shown, and all experienced surgeons are agreed that it is unwise to do any operations on poliomyelitis other than to correct deformity until two years have passed, because until about that time conditions have not become stable and it has served as a good working rule, but with further experience has come the doubt in the minds of many surgeons whether operation is not better deferred until three or four years or even until later childhood, and the latter point of view has gained ground of late. It is hard, however, to set a definite time other than the two-year limit for such varied operations as are performed for poliomyelitis. Some operations are merely the change of tendons, to rebalance the foot, *e.g.* and if these are deferred too long, bony deformity may be acquired and deterioration of stretched muscles may occur. It would seem as if a quantitative examination, such as the muscle test affords, might in the individual case afford much information as to the proper time for interference, and that in some cases two years would be quite long enough to wait in older children, while in others it might be wise to defer the operation in an attempt to develop certain muscles, and in younger children. On the other hand, the more destructive operations necessitating the extensive removal of bone are better deferred. In arthrodesis or artificial ankylosis, for example, many early operations have been followed by serious bony distortion resulting from the injury to growing epiphyses, so that so sound an authority as Robert Jones advises that no such operation should be performed until growth has been nearly completed. Tendon fixation and silk ligaments are not so much open to this objection and probably can be performed with safety in middle childhood. But the removal of the astragalus implies a good deal of disturbance in the mechanics of the foot, and is not in my experience best performed on young children, but rather in middle or late childhood.

Extensive operation is not, in my opinion, desirable in young children even in the case of tendon transference.

On the whole, the operative treatment of poliomyelitis is one of the most brilliant achievements of modern orthopedic surgery. Fairly recent in its development, it has passed through rather a florid period of over-development, followed by a time of undeserved depreciation, to emerge into a period of greater stability with an increasing agreement on the part of experienced men as to the relative value of the different operative methods. It is by all odds the most interesting part of the treatment of poliomyelitis, and I for one have to struggle continually to keep from becoming too much interested in this phase to the detriment of the routine treatment of the early phase, where I believe that ultimate function is more largely determined than in any other period of the disease.

It seems obvious that operation can in many cases be avoided by more accurate early treatment, that it is desirable to avoid unnecessary operation, and that when operation is to be done the results are likely to be better (especially in tendon work) if the case is exhaustively studied beforehand.

Many cases are destined for operation from the end of the acute attack and must be carried through the second stage with all care. The majority of all cases are not operative and never will be, because the paralysis is too severe or too slight, or so distributed as to render operation useless, while a third class become non-operative or operative in the third stage by the care, or lack of it, given them in the earlier stages. It is manifestly sound surgery to see that as many operations as possible are avoided by careful treatment. When fixed deformity is present it must always be corrected by operation except in lateral curvature of the spine, but as deformity is as a rule to be prevented by efficient care in the early stages, here again unnecessary operations are to be avoided by such care.

Table 1.—Result of Muscle Training

Patients treated daily at office by skilled assistants.

Age	Time Since Attack	Interval Covered by Tests	Average Total Gain of Affected Muscles, per Cent.	Average Monthly Gain of Affected Muscles, per Cent.	Apparatus Worn	Region Recorded
22	1 mo.	6 mos.	197	24	Sling	Arms
8	3 mos.	5 mos.	82	16	Corset, crutches, braces	Legs
9	3 mos.	6mos.	146	21	None	Legs
9	21 mos.	10 mos.	200	20	Plaster jacket, crutches, braces	Legs
14	4 mos.	4 mos.	688	172	Corset, braces, crutches	Legs
8	15 mos.	7 mos.	702	100	Corset, braces, crutches	Legs
8	3 mos.	6 mos.	184	30	Corset	Legs
Patients treated at home by relatives or nurses (unskilled).						
10	1 yr.	6 mos.	13	2	High heels	1 leg
30	5 mos.	1 mo.	44	44	Sling	1 arm
24	6 yrs.	3 mos.	12	4	None	1 leg
10	2¼ yrs.	8 mos.	108	13.5	Corset, plate	1 leg
11	6 yrs.	5 mos.	89	17	Plaster jacket, braces	Legs
4	1 yr.	7 mos.	30	4	Brace	1 leg
11	9 yrs.	2 mos.	33	17	None	Arm and leg
10	3 yrs.	4 mos.	16	3.5	High heel	1 leg
10	5 yrs.	7 mos.	None	None	High heel	1 leg
14	8 yrs.	8 mos.	67	8	Plaster jacket, brace	1 leg
16	2 mos.	3 mos.	620	206	Brace and crutches	1 leg.
8	1 yr.	7 mos.	202	28	Braces and crutches	2 legs, 2 arms

The question naturally arises, what evidence is there that the point of view here advocated is cor-

rect. What figures can be brought forward to show that this treatment has proved of value in any considerable number of cases. The figures presented are first from private practice and are given in Table 1.

Seven cases under daily treatment by an expert showed an average net percentage gain in muscle strength of 314 per cent. in treatment lasting from five to ten months, the average net monthly gain being 45 per cent. The duration of the paralysis at the beginning of treatment was from one to twenty-one months.

Twelve cases under treatment at home with unskilled assistance in the muscle training showed an average net gain of 103 per cent., with an average monthly gain of 29 per cent. These cases were of from two months' to nine years' duration when treatment was begun, with an average duration of three and one-half years, so that they may fairly be considered cases of the less promising class.

No cases where measurements were available were omitted from either table.

The presentation of figures will next be made from the Vermont observations. The cases in this instance were seen at clinics, of which three were held in eighteen months. Treatment was prescribed to be carried out by the parents with occasional supervision from one trained nurse skilled in muscle training who covered the entire state, encouraging patients to follow up treatment and changing exercise as occasion arose. Many of the families were ignorant and poor, living on farms without many comforts, isolated in winter and spring, and a less favorable ground for a therapeutic effort would have been hard to find.

In the cases seen in July, 1916, ninety-seven had followed treatment and sixty had not followed treatment to any degree. Certain data with regard to the two groups are available dealing with their progress in the previous year, or year and a half in some instances.

Table II.

Treated Cases, 97		Untreated Cases, 60.	
Unable to walk at outset	30	Unable to walk at outset . .	13
Able to walk now* (27)	90 per cent	Able to walk now (2) . .	15 per cent

Improved (clinically) (97)	100 per cent	Improved (clinically) (16) . .	27 per cent
Unimproved	0	Unimproved (44)	73 per cent

*Of the 27 now able to walk the conditions are as follows: Without support, 9; with braces, 8; with crutches, 2; with braces and crutches, 8.

Measurements as to muscle gain by quantitative measurements taken at intervals of one year ending in July, 1916, are available in fifty cases. Forty-six followed treatment to a greater or lesser extent and four did not follow treatment.

The average net gain in muscular strength in the affected muscles in the treated cases was 59 per cent.; the gain in untreated cases 17 per cent.

The term "net gain" means that having reckoned the percentage gain in the affected muscles the percentage of gain in the normal muscles was deducted from this. So that the term "net gain" means that the affected muscles gained faster than the normal muscles. In ten cases, however, it was classed as net loss, because although the affected muscles had gained, the normal ones had gained faster. In one case, however, there was a real loss of muscular strength in one year amounting to 11 per cent. This was a case of severe paralysis wearing two caliper braces, but having little other treatment. In no other case in the forty-six who followed any kind of prescribed treatment was there failure to gain strength in the affected muscles, and in thirty-six of these forty-five the affected muscles gained faster than the sound ones. The onset of these cases ranged from 1908 to 1914. Treatment was begun in 1915.

I have purposely avoided giving more detailed figures for fear of confusing you, and whether or not my figures bear out my contention in the beginning of the paper, that we are justified in holding out a higher degree of hope than heretofore, that thorough, persistent and long-continued treatment will produce results which are encouraging, I leave you to decide.

The impression that I should like to have you carry away as the outcome of this paper is that paralytic poliomyelitis is more often a weakening of the affected muscles than a total paralysis. As a result of this, conservation and improvement of such muscles must be our main treatment. That the use of braces is conservative and preventive rather than therapeutic. That of the therapeutic measures at our disposal for use in the convalescent stage, muscle training best meets the physiological and pathological requirements, but to be effective such treatment must be based on a thorough and accurate muscular diagnosis, and must be carried out with optimism, persistence and accuracy, and that the treatment under these conditions is effective in influencing ultimate function.

234 Marlborough Street.

SOME ASPECTS OF SPECIAL INTEREST BEARING ON THE ROENTGENOLOGICAL DIAGNOSIS OF TUBERCULOSIS OF THE LUNGS.*

By HENRY HULST, A.M., M.D.,
GRAND RAPIDS, MICH.

"The science of Roentgenology is in the interpretation of the Roentgenograms as applied to the diagnosis and prognosis of disease, just as the science of pathology lies in the interpretation of the slide" is the pronouncement of one who takes special pride in letting it be known that he is a specialist, that his specialty is that of Roentgenology. He is a Roentgenological diagnostician, therefore, of many medical and surgical specialties.

We have reached a stage in the evolution of Roentgenology in which we look down condescendingly upon the art of making Roentgenograms as no longer deserving, because no longer requiring the valuable time and personal effort of the physician. By a happy division of labor the technician relieves the Roentgenologist of what formerly took much of the doctor's attention, the mere making of pictures, during the first period, in reality the premedical period, of Roentgenology.

We have now entered upon the second period, the genuinely professional period. But I see a third period, the ultimate period, casting its shadow before.

As Cohn pointed out, "He will derive most as-

*Read by invitation of the New York Roentgen Society at its joint meeting with the Philadelphia and New England Roentgen Societies in New York, March 11, 1916.

sistance from Roentgenology who has acquired the greatest proficiency in clinical and physical methods of examination," so also the specialist, the real specialist who devotes himself heart and soul to one branch only of medicine or surgery, should be best able to interpret Roentgenograms pertaining to his particular specialty. This will constitute the period of benevolent assimilation of Roentgenology, and of the Roentgenologist too, by medicine and surgery. The division of labor which resulted in the differentiation between technician and Roentgenologist in the second period will go on logically, perhaps unmercifully, until every physician in the final period interprets his own plates.

But before this millennium is fully upon us, before the second-period Roentgenologist shall disappear from the face of the earth as an anachronistic, superfluous, moreover necessarily superficial and therefore more or less ridiculous middleman, and only physicians and technicians remain, I should like to remind you of two or three facts, lest we forget, and then consider some of the points of special interest just at present in connection with the Roentgenological diagnosis of tuberculosis of the lungs.

Roentgenology of the lungs dates back to the very beginning of the use of the rays. Thus Dr. Crane published in March, 1899, in the *Philadelphia Medical Journal,* his article on "Skiaskopy of the Respiratory Organs," one of the earliest detailed presentations of the subject in this country. At this period the fluoroscope was chiefly relied upon and was more useful, without a doubt, than Roentgenography, which was but poorly done. In 1899 but few Roentgenologists could take a lung in one minute. More commonly five or ten minutes were required.

It was in this same year that Rieder and Rosenthal (*Muenchener medizinische Wochenschrift,* 1899 No. 32, and *Fortschr. a. d. Geb. der Rocntgensts.,* 1899, Band iii) reported their method of making Roentgenograms of the lungs in one second or less by sandwiching a film between two intensifying screens. This constituted, not the beginning of, but the first great stride in advance in, the Roentgenology of the lungs. The beautiful atlas: "Die Roentgographie in der inneren Medizin" by Prof. H. Von Ziemssen and Prof. H. Rieder, published by J. F. Bergmann in Wiesbaden in 1901, was the first born fruit of this conception. How I admired those pictures with their wealth of detail as compared with the meager black and white gross shadow pictures of earlier days!

At the third annual meeting of the Am. Roentgen Ray Society, which was held in Chicago, Dec. 10 and 11, 1902, I was permitted to exhibit, though not yet a member, Roentgenograms of the lungs taken in one, one-half, and one-fourth second, with and without the use of intensifying screens. These were the first of the kind made and exhibited in this country.

The next year I read by invitation of the society at its Philadelphia meeting an article on "Skiagraphy of the Chest," which was published in the transactions of the society for 1903, together with a halftone reduction of the first one-second tuberculous chest without the use of intensifying screens, ever published here or elsewhere so far as I have been able to determine. As a rule my exposures even then were shorter than one second, but extremely short exposures were difficult to reproduce as halftone reductions. I have noticed, by the way, that for some reason not clearly defined, Rieder has gone back to long exposures for pulmonary Roentgenography.

You will pardon me for thus lingering fondly over this polliwog period of my Roentgenological career. In fact, I may as well confess it, there is still somewhat of the polliwog left in me, and at times I feel that some of our frogs matured perhaps rather prematurely.

As Snook took up a German idea and realized it in the modern interrupterless transformer which has made Roentgenography, especially of the lungs, much easier; as Coolidge revolutionized the Crookes tube and gave us the Coolidge tube, so we need some one, some other American if possible, to perfect the Dessauer Blitz-Apparat—a thing I have been urging manufacturers to do for years—and furnish us with the real article, an instrument that will enable us to take a lung, or stomach for that matter, in say one five-hundredth of a second without the aid of intensifying screens and without boring the target. We need it, and therefore we must confidently expect it will come about.

Now that we are graduating out of the first class of Roentgenologists and delegate the picture making business to assistants (nurses, "Sisters," boys, young ladies, medical students, and here and there perhap a genuine expert technician) and have more leisure for the professional study of plates, it is but reasonable to expect of us better interpretations.

It pleases me to state from personal observation that some by their superior work have justified this expectation. Too many, however, have not yet. Now there is a very good reason for this. We read marvelous tales of former polyhistors—men who were preeminent in botany, zoology, geology, psychology, mathematics, metaphysics, and theology—who knew a dozen or more dead and living languages and who were besides accomplished artists —artists in painting, music, sculpture, architecture —and artists of the logos: poetry, oratory, and literature. I have also come across physicians who serve as multi-specialists. The Dutch have a way of dubbing such pan-prodigies as "men of twelve trades and thirteen failures."

Now, it seems to me that the latter-day professional Roentgenologist is in a predicament somewhat similar to that of the encyclopedic polyhistor, polyglot, polygraphic, polypragmatic polyp of scholastic, prescientific days. He has too many irons in the fire. He has more specialties than he can manage. The real specialist does not, and cannot, take him quite seriously, and is only tolerating him good naturedly until he can permanently dispense with his services by taking upon himself to do the work that naturally and by right and reason belongs to him and to no one else. The Roentgenologist as such, according to my opinion and contrary to that of some present, is an artifact, a temporary by-product of medicine who in due time will fall by the wayside or find his way back into the regular ranks. Not until then shall the present Roentgenological epicycle be completed and the mission of the Roentgenologist be fully discharged.

It is as such a by-product myself that I approach the consideration of certain Roentgenological topics of pulmonary phthisis, as a Roentgenologist, that is to say, who would make use of the Roentgen rays as he may of the trocar, which likewise constitutes one means of diagnosis and of treatment, but likewise a poor basis upon which to construct a specialty.

At once we meet with serious difficulties. The average Roentgenologist, among whom I take my place, is not yet chiefly, and first of all, pathologist, as he should be. His knowledge of the underlying pathological processes is second hand, or largely so. He looks through other observers' eyes. His mind is biased by what he learns directly or indirectly from them. His apperception being determined by the second-hand mental furniture thus casually acquired, as much as by the dots, dashes, "splashes," "fans," "tobacco clouds," "interweavings," "mottlings," etc., which constitute his own special contribution to the work in hand, is it to be wondered at that a study of the literature of Roentgenology of the lungs, especially of incipient tuberculosis of the lungs, reveals the fact that the progress made is perhaps not quite satisfactory?

Until we can approach our subject from the viewpoints both of macroscopic and microscopic anatomical pathology and of clinical medicine, we Roentgenologists, we peculiarly situated middlemen, should be exceedingly cautious in our deliverances.

When a patient has a hemorrhage from the lungs and the plate shows nothing wrong except a dense spot in the hilus, it is not advisable to tell the attending physician that the hemorrhage is due to the spot opening a blood-vessel by scratching it by the movements of respiration. Such stunts do not promote usefulness nor enhance reputation.

Again, whether pulmonary phthisis is to be conceived of as primarily affecting the blood-vessels and is, therefore, hematogenous, as Aufrecht holds, or is of an aërolymphogenous nature, as Tendeloo maintains, or whether the primary process is acinousbronchial, are pathological questions which we as Roentgenologists should not consider incumbent upon us to settle. Of one such attempt at the third Roentgen Congress in Berlin, Holzknecht spoke sarcastically as a "taking by storm the diagnosis not only of tuberculosis of the lungs, but of its pathogenesis as well."

It is, however, an altogether different matter when a Roentgenologist notes agreement between his own observations and the findings of the pathologist, and undertakes to point it out. This I had the pleasure of doing at the 1911 meeting of the American Roentgen Ray Society, quoting Tendeloo as saying: "It has been accepted for a long time that pulmonary tuberculosis begins in the apex of that organ. But this is an error that has caused much confusion. Where do we find the foci? A primary tuberculous pulmonary focus often begins in the apex, but also often in other parts of the lungs. By far the most foci are to be found in the paravertebral cranial part of the lung, that is, in the pulmonary sector close to the vertebral column, cranial from the fifth rib about between the hilus and the apex, including the apex. The physician who examines but the apex and not the paravertebral cranial part of the lung does not fail again and again to overlook beginning tuberculosis."

This corresponds exactly with the region where early radiography most frequently detected changes. It is the domain of the vertebral branch of the upper lobe bronchus, the posterior division of which, according to the extensive investigations of Birch-Hirschfeld, is frequently stunted, distorted, and kinked. Schmorl recognized a groove caused by pressure of the first rib in adults and sees in this the cause of the stunting, kinking, and distortion of this particular division of the bronchus whose linear markings Dunham sees behind the first rib.

Bacmeister was able to produce in young rabbits an isolated apical tuberculosis in the region of Schmorl's furrow by causing a slowly increasing pressure-stenosis and subsequent direct and indirect hematogenous infection.

Tendeloo finds the primary foci in places where the respiratory movements of the lymph are slightest—"in peribronchial perivascular tissue and the under parts of the pleural and subpleural lymphatics, or in lymphadenoid tissue. . . . These movements depend on the respiratory movements of the air vesicles, which are not equal in all parts of the lungs: those of the paravertebral cranial vesicles are the slightest, and from here they increase in all directions."

Nikol accepts Tendeloo's observations on the respiratory movements of the air vesicles and their influence in creating a vulnerable zone which he locates, as does Tendeloo (and upon his authority), in the same region, though not in the same tissues, Tendeloo using his observations on the respiratory movements of the air vesicles to support his theory of the lymphogenous origin of pulmonary tuberculosis; Nikol adapting the same observations of Tendeloo for further development of his own bronchogenous theory. In inhalation experiments, dust settles in this region first and mostly, and it is the last region to clear up. Here Babcock locates his primary clinical focus, "a point about an inch or an inch and a half below the extreme summit of the lung and somewhat nearer its posterior and outer border." "From this," he continues, "it spreads downward and backward and hence should be sought for in the suprascapular region, since clinical signs of disease may be discovered here before they appear in front. From this primary focus the lesions often spread downward along the anterior aspect of the upper lobe, about three-fourths of an inch within the margin, frequently occurring in scattered nodules, separated perhaps by an inch or more of healthy tissue. It is not unusual to find in these scattered nodules the only evidence of disease of the lung when posteriorly excavation has advanced to such a degree that but little more than the pleura remains."

Such correlations as these are useful to the Roentgenologist in his difficult task of reading plates. But what we really need is a rounded-out conception of the pathogenesis of pulmonary phthisis, a macroscopic if not a microscopic consistent pathology as a common basis upon which clinician and Roentgenologist can meet, understand each other, and cooperate. The language of the plate is not in terms of râles and resonances, but refers to visible lung changes; it is of sight, not of hearing. Both constitute systems of symbols, and as such both are more or less unreal. Unfortunately, we cannot put them on a graphonola or Victor machine and by means of steel needle interpret by retransformation. Nor can we profitably read one set of symbols in terms of the other. Both râles and resonances on the one hand and the cabalistic configurations of the Rooentgen plate, on the other, speak of more or less gross lung changes, the exact character of which must be left to the pathologist, not the Roentgenologist, to determine. He is the logical umpire.

If men like Aufrecht, Tendeloo, and Nikol would add Roentgenology to the other physical methods employed by them, we should soon be in possession of a body of facts useful to both clinician and Roentgenologist. And now that the pathologist can hire a technician, there is nothing to hinder him

from doing this, and we may look to more rapid progress in the future. Meanwhile we Roentgenologists shall have to continue to cross-question the pathologist and try to correlate as best we may our own hieroglyphics with the direct information he may give us.

What, then, are some of these Roentgen signs and what do pathologists offer that may help us to recognize and to name them?

First of all, let us listen to Dr. Kennon Dunham: "I am sure that the increase in the hilus shadows, the thickening of the trunks, together with such alterations in the linear markings as increase in density and breadth, studding, interweaving, and extension to the periphery, constitute a shadow picture characteristic of early tuberculosis. . . . If the linear markings in the limited area are sharply defined and dense and show clear cut studdings beyond the trunks, a healed lesion is suggested. . . . The moderately advanced and advanced cases of pulmonary tuberculosis are readily recognized. In the less advanced cases careful study will disclose the alterations in the linear markings, heavy trunks, and hilus shadows previously described. If in such cases the fine linear markings of certain trunks are fuzzy or seem to merge to form a cloud effect, such as a film of tobacco smoke, active tuberculosis would be suggested." This describes in Dunham's own language a Roentgenographic vision which all have seen, no doubt, but which he has singled out as no one else has done and which he uses as a key with which to decipher the Roentgen code of pulmonary phthisis. For this and for his volume of stereoroentgenograms illustrating his theory, he deserves great credit, no matter what the final verdict as to their significance may be.

By way of contrast let us now compare with Dunham's characteristic Roentgen signs those of F. S. Bissell and E. T. F. Richards: "The earliest and only characteristic Roentgen signs of pulmonary tuberculosis are minute islets of increased density which tend to group themselves in a typical manner in certain elected localities in the lung. . . . These are Roentgenological tubercles. . . . Their first points of election appear to be (*a*) in the first and second interspaces near the median triangle and (*b*) toward the periphery of the lung near the angle of the scapula. . . . As the process goes on to repair, with hyperplasia of fibroblasts and the formation of connective tissue, the field in which the tubercles lie becomes much broken in appearance and marked by interweaving striæ of increased density. This 'network' may remain after the lesion has healed and all evidence of tuberculosis has disappeared, so that we do not consider its presence alone of diagnostic value. We must remember, too, that fibrosis and thickening of the bronchial arborizations may be the result of other irritants than those due to the bacillus tuberculosis, and as we have encountered this 'network' so frequently in other lung infections we have come to consider it of little value except as a corroborative sign. . . . It is apparent that many men rely entirely upon this broken field for their early diagnosis, and this must inevitably lead to many errors." These authors, basing their conclusions on 219 cases, recognize, as well as Dunham, that "an active or recent lesion is much more prone to appear in continuity with a chain leading towards the hilus."

Assmann points out that whereas formerly the examination of the apices was considered of prime importance, the region below the apex, between hilus and clavicle, at present receives more attention. But since he, too, considers mottling the most important early Roentgen sign, as Grau has shown, and since these mottlings are often obscured in this region by dense hilus ramifications, he prefers the apex plate to bring them out more clearly than is possible elsewhere.

According to Rieder: "The extension of the tubercular disease or the flaring up of a latent tuberculosis acquired in infancy takes place, as Roentgenological investigations prove, not only in children, but also in adults, from hilus outward and not from the apex. Its farther extension, often on both sides, follows the three larger hilus ramifications, most frequently the upper, less often the middle, seldom the lower branches."

Byshell regards "definite mottling and nodules at the roots of the lungs as the only reliable evidence of tuberculosis." Melville expresses himself thus: "The one and absolute evidence is the presence in part or parts of the lungs of the characteristic fine mottling."

Jordan thinks that the linear shadows may be traced even to the periphery of the chest in healthy persons, but that mottling is the evidence of active disease. Hence, he cautions us not to diagnose phthisis "unless you can show mottling through a small aperture and show it on a photographic plate."

It would be instructive in more ways than one, and besides highly interesting, to submit to all of the authors quoted a series of plates of early tuberculosis for description and interpretation. Each would go at it according to what psychologists call, I believe, *his apperceptive mass.* That, of course, is inevitable. I imagine Dunham gazing into the mirror of the stereoscope and saying: "I see characteristic fan-shaped densities which extend from the pleura to the hilus with the apex of the triangle toward the hilus; the base of the fan is outward and backward behind the first interspace; the linear markings are replaced by an intricate fine network which is veiled somewhat as if by a cloud of tobacco smoke. What I see is characteristic, that is, pathognomonic of early tuberculosis."

If his friend, Dr. Wolman, were present he would undoubtedly remark (and this in his actual language): "I conceived at first a profound distrust of diagnoses that had to be based on Dr. Dunham's peculiar stereoscopic markings. But now I can testify to my conversion to a belief in these same scorned markings, these mysterious markings for which we know no acceptable explanation. However, after subjecting them to a severe *clinical* test. I can state that undeniably they possess empirical truth."

Baetjer, no doubt, on hearing this would repeat what he has said before: "This method of diagnosis is empirical, as Dr. Wolman may well say, and has no known pathological basis, and has been substantiated by clinical findings only. Now it seems to me that this is the point where error could so easily creep in. Clinical findings do not constitute absolute proof. Besides, it seems to me that any chronic infection of the lungs could just as easily produce changes in the bands which carry the artery, vein, and bronchus. In emphysema and chronic bronchitis we see a marked thickening of these bands extending throughout the lungs. I agree with Dr. Dunham that the irregularities along these linear markings, which he has termed 'fuzzy,' are collections of small tubercles, but they are seen in a later stage of the disease."

Assmann looking over the same plates would agree as to the final diagnosis, but not until he had supplemented the examination of the stereograms with a minute scrutiny of apex views of the same case; because the hilus strands are dense and obscure the mottling, which he also insists upon as the characteristic, and only characteristic, Roentgen sign, if there be such, of early tuberculosis of the lungs.

All others present would concur in the final diagnosis, but they would reach it by different approaches. Even Rieder, while on the lookout for his particularly own Roentgen signs of cavitation in early tuberculosis—and probably finding them, too, while others overlooked them through lack of equal preparedness of their apperceptive masses—even Rieder would not be likely to overlook Dunham's "fan," for he seems to be quite familiar with it in all of its details. In his book (Rieder and Rosenthal, Fig. 31, page 278) he gives one of his characteristic schematic representations of it. His own pathological bias, however, must be held responsible for his description of the interweaving part of the fan as "net-like branchings of swollen lymph-vessels."

The other day, talking with a friend about characteristic Roentgen signs of early phthisis I noticed he used the word "characteristic" in a sense peculiar to himself. He contended that the words "characteristic" and "pathognomonic" meant different things. Nor would he yield the point until he was shown in Webster: "Pathognomonic, Med. characteristic of a disease."

Now, it occurs to me that after listening to all of our Roentgenological authors with keen interest and thorough appreciation of the excellence of their work, many of us present might feel that their differences, after all, were less vital than their agreement and that the difficulties may perhaps be partly due to misunderstanding—a matter of language, of English, which Professor Wenley says is "entirely inadequate for purposes of philosophical expression." Differences that cannot be accounted for on this score may, for aught I know, be charged to diversity of apperceptive masses.

The question is still an open one, therefore, whether there are such things as pathognomonic Roentgen signs of pulmonary tuberculosis. Bandelier-Roepke, for instance, maintain that there is nothing in an *x*-ray plate of a tuberculous lung that is characteristic or pathognomonic of the disease. Strictly speaking, no doubt this may be true. The direct diagnosis of tuberculosis of the lungs by means of Roentgenography, like the direct positive diagnosis of ulcer of the bulbus duodeni, may be, "strictly speaking," unwarranted. For the sake of argument we may admit that just as other lesions besides an ulcer can produce "characteristic" bulb deformity, so also the "characteristic" signs of pulmonary phthisis may be produced by other pathological processes. Well, neither are there, as Babcock points out, auscultatory phenomena which are pathognomonic of early tuberculosis. Practically, however, we shall seldom go wrong in the case of pulmonary tuberculosis, especially, if, instead of relying exclusively on one so-called characteristic sign, we look with a thus enlarged apperceptive mass for all of the characteristic signs known or possible. For it is a fact of which we as Roentgenologists may well be proud, that in spite of all difficulties inherent in the problem itself and of those growing out of the subjectivity of the examiner, a striking unanimity of final diagnosis is reached when variously disposed and predisposed experts examine the same plates. This is in happy contrast with what Babcock, himself a well-nigh preternaturally expert percussor, says of percussion, which by some is considered equal or superior to Roentgenography: "So much depends upon the skill of the examiner in practisting this mode of chest examination that two or more men may draw different conclusions from percussion of a case at the same sitting."

We are approaching, though we have not yet reached, direct diagnosis. Careful Roentgenologists will render such tentatively only. But, of course, we cannot rest satisfied until this, too, can be done, both positive and negative, and that unhesitatingly. Some characteristic Roentgen sign always present, always recognizable, never due to anything else, even though empirical, would do. But while waiting for pathology to determine the archetypal basis needed for interpreting the ectypal Roentgenogram, which must take some time, may it not be possible to discover a heuristic principle, some temporary working hypothesis to help us out? Anything relatively fixed is better than wind and waves.

Classification such as that of Cornet, which reduces the polymorphous lung changes of pulmonary phthisis to two main processes—tuberculous peribronchitis and caseous pneumonia—and which also does justice to Orth's conception of the dualistic nature of the histological changes involved as proliferating and exudative, has in its favor that it is at least simple.

The main objection to this division lies in the vagueness of the conception "peribronchitis." This also applies to Assmann's assumption that the peribronchial tubercle constitutes the prototype of all tuberculous lung changes. For the same reason Nikol takes pains to show that Ziegler describes as *bronchopneumonic nodules* lesions which Orth designates as *tuberculous bronchitis and peribronchitis*, while Abrikosof, who constantly speaks of bronchitis and peribronchitis, seems to identify peribronchitis with *Lymphangitis tuberculosa peribronchialis*.

Assmann adds to the confusion when he classifies his peribronchial tubercles as miliary tubercles, a term which is reserved by common practice to the hematogenous variety, though it is true that it may be difficult at times to distinguish between the two upon the Roentgenogram.

Assmann cautions us not to regard the Roentgen appearance of miliary tuberculosis as pathognomonic, and reports a case of bronchiolitis obliterans, diagnosed clinically and Roentgenographically as miliary tuberculosis, the real nature of the lesions being revealed at autopsy. He also tells of a post-mortem on a patient who had died of puerperal septicemia whose lungs were studded with minute abscesses of the size of the head of a pin, which probably would have appeared on the plate like miliary tubercles. Unfortunately, a Roentgenogram was not made. But aside from rare instances such as these, and possibly of miliary carcinosis, the more or less distinct general mottling of disseminate miliary tuberculosis constitutes a Roentgen sign of tuberculosis that is well-nigh pathognomonic.

A Roentgenogram of the lungs shows hilus, hilus ramifications, and parenchyma. No matter how biased, whether we believe the bronchi, the lymphatics, or blood-vessels to be chiefly or primarily involved, we satisfy the demands of bronchogenists,

lymphatogenists, and hematogenists alike if we approach the study of the Roentgenogram by way of the hilus ramifications in all cases not clearly miliary. These ramifications represent the triple track military highways which the invading enemy must take. In these or in their vicinity we must expect to find the early signs of his trenches.

We may specify farther: Since Tendeloo, Birch-Hirschfeld, and Nikol, though they disagree absolutely on the pathogenesis of pulmonary phthisis, are agreed that what Tendeloo has determined to be the area of the greatest biochemical susceptibility is also first involved, we have good reason for concentrating our attention upon this area.

Tendeloo's region corresponds to the hilus and hilus ramifications which follow the course of the upper vertebral branch of the upper lobe bronchus, and it is interesting to note that Roentgenologists have long ago learned to look upon this indentical region as the one to be suspected before all others—not from any pathological or clinical bias; in fact, in spite of clinical teaching, but because their experience very soon taught them to look for changes where they were found most constantly and most abundantly in early cases.

Necessarily, the first changes to attract attention were those of the regional glands, of the dustbins and lethal chambers, as some one has aptly called them, that drain the area of greatest biochemical susceptibility.

With the advent of short exposure technique, changes were detected along this ramification higher up as well, often of a more delicate nature, until now the distal endings reveal even more characteristic changes than does the hilus. At the periphery the bacilli are first halted and the earliest signs in adults are to be expected there.

In children, according to Gohn, and as is now well regnized, the location of the primary focus is much more inconstant, Gohn's tubercle may be found almost anywhere. According to Gohn himself, it is located most frequently in the anterior portion of the upper lobes—just the opposite from the adults—and in the posterior portion of the lower. It may be actively progressing or more commonly obsolete, frequently very small, a mere little scar, though the tracheal and hilus glands show extensive and rapidly progressing involvement, as if on account of the greater permeability of the mucous membranes and better functioning lymphatics of children the bacilli are swept almost immediately into the dustbins at the roots of the lungs.

Not only as depending upon the age of the patient, but also as directly and inversely proportional to the virulence of the infection, and the inherited and acquired resistance of the host, the type of the disease must differ from the very start. We should expect to find, therefore, early signs of acute and of more chronic forms both, and look for them not merely in one location but everywhere, according to age and circumstances.

Combinations of various pathological conditions occur in one and the same case. One form of the disease may change into another. Chronic types become acute, and vice versa. To note density differences, hence to distinguish, constitutes the very life and soul of Roentgenology, a reason the more why we should purposely guard against making too sharp distinctions, as against a tendency growing out of the very nature of our work—lest it become a bad habit.

With this caution and with the exception of miliary tuberculosis and the special type of the disease common to children, we are justified in assuming, therefore, that the early lesions will be found as described.

Of the several types of early lesions as well as of more advanced forms of the disease, Assmann has published good illustrations. Dunham has not found it possible to reproduce the earliest lesions as stereographic reductions on account of the difficulty and expense, and gives only two illustrations of "early" tuberculosis.

Since, as we have seen, the location of the early lesion is determined by the hilus ramifications, that is to say, by the anatomical structure of the lung itself, the suggestion arises that its histology also may depend upon the same general factor. The results of Nickol's investigations make it highly probable that this is, indeed, the case. He finds that the most typical of all lung lesions, the acinous nodular focus, depends for its location and macroscopic and microscopic appearances upon the anatomy of the structural unit of all lung tissue, the lobulus.

This lobule is made up of an intralobular bronchus giving off two or three collaterals and two terminal bronchi with their dichotomous bronchioli, each again giving off smaller branches. The terminal structure is the acinous bronchiolus. This corresponds to the bronchiolus respiratorius, as given in Quain's "Anatomy." Here the alveoli begin and ciliated epithelium leaves off. Each bronchiolus gives off three or four alveolar passages. An acinus, therefore, is the domain of a bronchiolus respiratorius with the alveolar passages appertaining to it. Acini are more uniform in size than lobuli. A lobule contains from fifty to one hundred acini. Lobules do not anastomose, but interdigitate with each other, as do also their accompanying lymphatics and blood-vessels.

The bronchiolus respiratorius is first involved in acinous tuberculosis, as well as in non-tuberculous bronchopneumonia. The acinous foci conglomerate into small and larger-sized nodules. From the start there is apparent a tendency toward induration and hence this form belongs to the chronic and subacute variety.

Macroscopically the acinous nodular focus appears as a conglomerate of small greyish blue bodies which look like miliary tubercles. They differ in that miliary tubercles are more evenly distributed over the entire lung, diminishing in size from apex to base, while acinous foci occur in groups at the end of the bronchi and form clover leaf and rosette-like bodies.

These foci have hitherto been variously described as peribronchial tubercles—Assmann; or as walnut sized and larger foci of fibrous groundwork, in which gray or yellow nodules of the size of a millet seed are imbedded—Orth.

The distal portion of Dunham's "fan" is probably made up of acinous nodular foci of Nikol, the central induration obscuring the nodules and accounting for the clouding.

The rosettes of millet seed sized nodules, softer and earlier, may stand for the islets of mottling so strenuously insisted upon by most others as an earlier and even more characteristic sign.

The leaves (mottling) which hide the branches in spring and summer, after falling, leave the bare branches standing out boldly as against a clear sky when healing has taken place.

Viewed after this manner, the acinous nodular

focus assumes preeminence as the prototype not only of one form of chronic and subacute phthisis, but of caseous bronchopneumonia and tuberculous bronchitis as well.

The acinous nodular focus thus becomes the keystone which finishes and supports the entire pathological arch and the key to the crypto-Roentgenogram. How this is accomplished by Nikol for pathology and how to correlate the data thus obtained with those of the plates, we have no time now to pursue any further.

Enough, if by condensing the fog I have succeeded in a measure in clearing the atmosphere, and by pointing out a way toward a more consistent and comprehensive view, I have contributed to a better understanding among ourselves.

100 Fountain Street East.

THE MEDICAL MIND.*

By JAMES M. PUTNAM, M.D.,

BUFFALO, N. Y.

During the thirty-odd years which have passed since I received my diploma, I have naturally had many opportunities for the study of the Medical Mind, or if you please, medical psychology.

We are a curious mixture of heredity and environment—a curious blend of optimism and pessimism. Our heritage is a glorious one for we present an unbroken line of professional workers with one ideal which was old before the Christian era. From the time Hippocrates taught his disciples at Cos to the present, the one great idea, the one great controlling thought has been to find the truth and, having found it, to use it for the benefit of mankind. The truth sought for has never been sought that it may be put to the base use of man's destruction.

Of all the sciences, medicine has always worked and studied that the lot of man might be easier—that the diseases which threatened the human race might be checked, that the inhospitable climes might be made fit for the human abode. But of all the sciences, medicine alone has never had as its goal the discovery of agents for the destruction of man. We have never prostituted our mighty enginery to the destruction even of an enemy. This is, indeed a glorious heritage and one we must not lose sight of. In all the ages and in all civilized lands we have been bound together by this mighty purpose into a common brotherhood. The discoveries and researches of each are the common property and interest of all—no discovery anywhere, by anybody, at any time, in the healing art or in the preventive art but is of vital interest to all. So true is this that a common purpose has verily knitted the profession into a solidarity unknown to the theologians or to the jurists. What does the lawyer care about the law of another country—it does not effect his practice nor his methods. With us, on the contrary, if a German, Erlich, discovers a method of treatment as by salvarsan; if a Frenchman unlocks the door of mystery and Pasteur gives the key to the treatment of rabies; if an Englishman, Lister, solves the riddle of wound infection; if an American, Gorgas, by a system of sanitation makes the pestilential Isthmus of Panama a health resort and banishes the scourge of yellow fever—these leaders proclaim truths of interest to the medical world, and every physician of the world is the gainer.

*President's Address delivered before the Buffalo Academy of Medicine.

This brotherhood is, however, a far closer bond than the bond of common possession of truth or of aims. We have a sense of mutual aid. The assistance which the humblest of us in time of sickness can command from the greatest is another of our blessed heritages. It is true that the burden sometimes is heavy and that some have been severely taxed, but as Weir Mitchell once said, "I have cheerfully paid it all."

We have still another inheritance which we have had so long that by common consent society does not dispute it. I mean the care of the poor. It is not enough to say that we are repaid by the experience we gain. although it is true we gain some experience, but no other profession so universally, so continuously does its charity on such a wholesale scale. No, there is something else which keeps us at the work, something else beyond scientific ardor. It is the love of humanity. It is best seen in the villages and small settlements. It is best described in the "Bonny Brier Bush." The Medical Mind is influenced by these strains of heredity. Our environment has often caused serious rifts in the brotherhood because, above all things, we are human. We are critical, skeptical, credulous. Let some toiler and earnest worker discover a truth and give it to the world. Its reception makes interesting reading and causes us to wonder at the strangeness of the human mind. Harvey announces the circulation of blood; Jenner gives vaccination to us; Morton gives us anesthesia; Oliver Wendell Holmes shows us the cause and prevention of puerperal fever. All these and innumerable others are met by ridicule, angry opposition, and abuse.

It is not that the medical mind does not welcome the truth. It is that we are slow to see it—that we have been thinking in grooves for so long that it takes years before a new manner of thinking can be developed. Also another psychic factor is involved. Often a new view is discreditable to the rest of the profession. Self-esteem is wounded. Could any pronunciamento have hurt more than Holmes' paper when he bravely announced that the physicians themselves carried puerperal fever on their hands from childbed to childbed. This is so interesting a chapter that it will bear a little further reading. Holmes published his essay on the Contagiousness of Puerperal Fever in 1843. The two leading professors of obstetrics in America, Drs. Hodge and Meigs of Philadelphia, abused him in language which has been described as something worse than the fair severity of hostile arguments, but fortunately the medical discussion did not lose itself in personal quarrel; fortunately for the multitudes of mothers, Holmes kept his temper, saying "every real thought on every real subject knocks the wind out of somebody. As soon as it comes back he very probably begins to spend it in hard words." He said, "I take no offense and I make no retort. No man makes a quarrel with me over the counterpane that covers a mother with a new-born babe at her breast. There is no epithet in the vocabulary of slight and sarcasm that can reach my personal sensibilities in such a controversy. Let it be remembered that persons are nothing in the matter. Better that twenty pamphleteers should be silenced than one mother's life should be taken. The teachings of these two professors in the great schools of Philadelphia are sure to be listened to. I am too much in earnest for either humility or vanity, but I do entreat those who hold the keys of life and

death to listen to me for just once. I ask no personal favor but I beg to be heard in behalf of the women whose lives are at stake until some stronger voice shall plead for them." He knew that he had "planted the seed of truth and that it would grow —the assaults only watered it."

These quotations are from Holmes' introduction to the pamphlet which, in answer to his opponents, he published in 1855, being a reprint of the publication of 1843. That this benefaction to mankind was always a great satisfaction to Holmes is but natural, and years later in an essay he referred to it thus: "When by the permission of Providence I held up to the professional public the damnable facts connected with the conveyance of poison from one young mother's chamber to another's—for doing which humble office I desire to be thankful that I have lived, though nothing else good should ever come of my life, I had to bear the sneer of those whose position I had assailed and as I believe at last demolished, so that nothing but the ghosts of dead women stir among the ruins."

I have quoted at length this passage at arms because it illustrates the difficulty which truth has to gain admittance when it knocks at the doors of professional prejudice, also because of the emphasis it gives to the valuable heritage we possess in claiming brotherhood with a spirit like this. It seems to me that it is not altogether a fault that we are slow to receive new ideas. It is far better to be critical than credulous. All that is new is not true. On the contrary, much more is false. One injunction of Holy Writ we must always follow, "Prove all things." If there is any tendency at present in the medical mind which must be guarded against it is the too ready acceptance of things not proven. An instance in point is the too ready acceptance of new products of laboratories of sera and vaccines, a great tendency of the present generation of physicians, and this is due to the environment and is a tendency to let others do their thinking. It may be better for the patients, but it is a habit which dwarfs individual mental growth. It is difficult for the medical mind to weigh evidence. Few of us have analytical power. Many of us are too lazy mentally to use what we have. Some of us are too engrossed in the drudgery of the profession. The reasons are many, but the tendency is one that must be fought.

In the domain of psychiatry a recent idea known as the Freudian theory is a good illustration of my meaning. This theory is being carefully studied by practically every psychiatrist and neurologist. It is earnestly discussed. It has its advocates and its opponents, but everywhere there is an evidence of a desire to arrive at the truth. In obstetrics the same scientific spirit is shown in the study of the merits of so-called twilight sleep. In ophthalmology the profession has patiently studied and weighed the evidence for and against the effects of refractive errors and muscular imbalance upon health.

Now dentistry is claiming the same earnest attention and the influences of pyorrhea and mouth infections are being weighed in the balance of criticism. Our studies, because of the close environment in which we live, are bringing us nearer the people. They know of the new discoveries as soon as we do and they expect us to use them. Mental unrest, therefore, is a psychic quality of the medical man. We were satisfied yesterday—to-day someone announces the radiograph—to-morrow we are asked to use it. The Curies discovered radium, the lay press publishes it, and the harassed physician is asked what he thinks about it—so that the psychology of the physician, due to his environment, must include a certain alertness and up-to-dateness, and right or wrong he is expected to have an opinion. It seems to me that we need to counsel together and get our bearings that a reasonable mental attitude is that of "watchful waiting," but we are not justified in sitting still and letting others prove it to be false or true, if it is in our power to help.

Our environment is crowding us along lines besides the healing art. Everything that tends to the perfecting of the body development or to the unfolding of the infant mind has come within our province, so that to-day the physician must add to his sphere of interest some knowledge of the principles of physical culture, open air schools, and systems of pedagogy. There is now no danger that the medical men will become one-sided, because the list of side interests is steadily growing longer and more formidable. The law is now closely allied to medicine so that the physician and the lawyer are bound to have common interests in the future. This is because it has been necessary for courts and commissions to have medical opinions on a variety of subjects pertaining to jurisprudence in the probate of wills, criminal cases, the extent of injuries, the estimation of the defects of different disabilities—this last being made necessary by our Workmen's Compensation Acts.

These responsibilities are put upon us and we must not shirk them. The cause of justice demands that these duties be honestly and fairly met. The physician must bring to bear judicial qualities and he must bring all his experience and reading to his aid. That the medical mind has failed to meet the requirements is a common taunt—that it is the fault of the environment and the method of the court is our answer. That the physician means to be honest but does not know how does not satisfy either our critics or ourselves. It may not be unprofitable to review a few of the scathing opinions of experts as given by judges.

Of late years there has been a growing distrust of all experts and a feeling against the admission of their testimony. To better show how authors view the subject I quote. Wharton on evidence, Section 454, says: "When expert testimony was first introduced it was regarded with great respect. An expert was viewed as the representative of a science of which he was a professor, giving impartially his conclusions." Two conditions have combined to produce a material change in this relation: (1) In matters psychological, there is no hypothesis so monstrous that an expert cannot be found to swear to it on the stand and to defend it with vehemence. (2) Then the retaining of experts by a fee proportioned to the importance of their testimony is now as customary as is the retaining of lawyers. Hence it is that, apart form the partisan character of their opinions, their utterances, now that they have as a class become the retained agents of the parties, have lost all judicial authority, and are entitled only to the weight which sound and consistent criticism will award to the testimony itself.

Lord Kenyon used the following language: "Skilled witnesses come with such a bias on their minds to support the cause in which they are embarked that hardly any weight should be given to their evidence."

But that is an English opinion of English experts;

you may think we stand better over here. Let me disabuse you by quoting Judge Davis of the Supreme Court of Maine in the Neil case: "If there is any kind of testimony that is not only of no value, but even worse than that, it is, in my judgment, that of medical experts. They may be able to state the diagnosis of a case more learnedly, but upon the questions whether it had at a given time reached a stage that the subject of it was incapable of making a contract or irresponsible for his acts, the opinions of his neighbors of men of good common sense would be worth more than that of all the experts in the country."

Stephen in his criminal law, page 209, says: "I object to the proposition of referring scientific questions to them (experts)." In this way has the medical profession of England and America dishonored the trust put upon it. Our judges say our opinions are bought and sold like any other commodity, and after it is given it is worth nothing.

What has brought about this discredit? Is it that we are less fair-minded and judicial, or is it that we are less honest than are the experts of France and Germany? For in those two countries we find no such distrust.

Another point of contact with our environment which vitally concerns us is our relation and our duty to our country. The times in which we live are no more strenuous and not so critical as those first years when Dr. Benjamin Rush signed the Declaration of Independence, or when Dr. Joseph Warren commanded the troops at Bunker Hill, or in the war of 1812, when Dr. Cyrenus Chapin led the patriotic band in Buffalo. At no time has the need of the country lacked the support of physicians. We have no need to be ashamed of the professional record. In all positions of danger and hardship the doctor has never been accused of lack of courage or of devotion to his duty. When the call has come it has always been answered. To-day the call has been issued again in no uncertain tones. We are called to help in the cause of preparedness. That preparedness is to put the country in such a position of safety and security from invasion that we are forever safe from aggression and insult from any nation on the face of the globe. There is no call for preparedness to carry on a war of conquest, but a preparedness to defend our shores. There is a group of citizens who object to this. They are of the same type of mind as those who object to vaccination against typhoid fever or smallpox. The medical mind, by training, believes in prevention and must necessarily believe in national as well as individual preparedness. But faith without works is dead; we must not only believe in this, but as individuals we must help bring about that preparedness which will get us out of our present state of defencelessness. We must help convince others. I urge you that as a profession we present a solid front on this question.

The medical mind, gentlemen of the academy, must show itself true to its glorious heritage, loyal to its environments and loyal to our country. We should certainly consider the medical needs which the enlarged army calls for. We must impress upon our minds and the minds of the young men just entering the profession the fact that the army and navy medical service is an honorable and useful scientific service. Many of the important medical advances have been made by army surgeons and none more notable than that of Surgeon Beaumont upon Alexis St. Martin. I have always been as much impressed by the mental caliber of Beaumont by his patience, by his readiness to seize the wonderful opportunity which presented itself, by his real and untiring energy, as I have by the importance of his observation.

In arranging my impressions of the medical mind and the influences which have shaped it, my hope has been that we might realize the great opportunity for our influence that the present offers, and that we should show that the united profession must conscientiously labor for the preservation of peace and the prevention of war, by a thorough national and individual preparedness for war and that we may do our share toward bringing about the Parliament of Nations and the Brotherhood of Man.

TREATMENT OF FLAT-FOOT IN OLD PATIENTS.

By SIGMUND EPSTEIN, M.D.,

NEW YORK.

ORTHOPEDIC CHIEF, GERMAN POLIKLINIK; ORTHOPEDIC ASSISTANT, MOUNT SINAI DISPENSARY; ORTHOPEDIST TO THE BRONX DISPENSARY.

Albert Hoffa wrote that the treatment of flat-foot was one of the most gratifying things in orthopedic surgery; efficiency tests of clinical results of fourteen years' work, however, have brought to notice a number of exceptions to the smooth and prompt relief of pain, so that a study of my early mistakes is valuable. In the bright lexicon of youthful flat-foot there is no such word as fail; but in patients after middle age, we have our limitations and complications—hence this honest orthopedic confession.

In the wintertime of life painful affections of the feet require careful differentiation. Our patients are then most exacting, and it is possible that they and their foot ailments are less understood. More time is necessary in diagnosis, the psychological element looms up as an important factor, and in a busy orthopedic clinic, time does not permit the personal and economic study of old men and women. When the busy medical adviser, to whom all burdens are brought, loses his patience with his elderly clients and their chronic diseases, they are prone to depression, accentuated by their apparent helplessness.

To begin with, old age itself is a condition that must be reckoned with when the treatment of a case of foot disability is undertaken. Many changes take place in all the bones, the cartilages begin to atrophy, there is less joint lubricant, there is a progressive thinning with calcification of the capsular structures of the joints, and we say that the patient is becoming stiff in these articulations. Even the spine begins to stoop, the intervertebral discs thin out, and the stature is diminished. The angle of the femoral neck with the shaft becomes more acute, and the stride becomes shorter; the head droops a little and the knees bend. The *x*-ray shows that the bony striæ are thinner and sharper in the medullary portions; "toothless old age" is due to this essential atrophy. Furthermore, a number of conditions, weaknesses, or dyscrasias, can conspire to bring about serious arthritides of longer or shorter duration after a slight traumatism. In youth, the effects of a strain are scarcely noticed; bruises and wrenched joints quickly clear up and are soon forgotten. In old age, we have to consider senile arthritis, osteoarthritis and arthrosclerosis (Noscher); these are

often traceable to nothing else but the altered and delayed processes of growth, evolution and retrogression of cells.

Clinically, there are many types of senile osteoarthritis. Many authors have attempted pathological and bacteriological classifications; some have as a basis chemical findings; some attempt to group them by their radiological appearances, while the rheumatoid group have as a basis the mode of onset. Sometimes we find that a given case presents characteristics that place it in several categories. When each case is considered by itself, then the patient receives the most benefit, exactly as he should when chronic conditions make their appearance in any other system of organs.

In the foot, a senile arthritis may affect any of the tarsal or metatarsal joints; the ankle presents swelling, effusion and stiffness, while pain on bearing the weight of the body is an early symptom. Later, there is bony thickening, creaking, limited mobility, capsular tenderness, and all the signs of partial or complete adherence of joint surfaces. The metatarsal bones being thinner, smaller and more subcutaneous, will show excresences in the form of bunions and prominences of the instep and of the ball of the foot. The experiences that patients narrate, in their quest of the boon of painless feet, illustrate the futility of treatment that is not based on a sound knowledge of the anatomical and pathological changes at the bottom of the difficulty in locomotion. One man told of having consulted thirty physicians, masseurs, water-cure and electric-cure practitioners.

If a flat-foot is swollen, and complicated by a condition of affairs such as I have attempted to describe, it is useless to decree the wearing of a pair of rigid Whitman plates without preparing the extremities for their reception and proper use. We must not lose sight of the fact that the condition is one of a progressive, painful, complication of flat-foot, an inflammatory process attended with exudate and bony thickening. The mechanical principles of treatment must often be postponed until accessory hygienic and medical aids are applied. For instance, we can have recourse to rest in bed for a period, with or without plaster-of-Paris retention, under a dietetic regimen; eliminative and analgesic measures then do most good.

When function is again permitted some old people would rather have a pad of corn plaster felt under the arch of the foot than any plate that has ever been designed. In other cases, especially after ankle fracture, the wearing of an ankle brace extending to the knee, is the only way of putting an elderly man on his feet. Writers have repeatedly drawn attention to the tendency of practitioners to put up malleolar fractures without safeguarding against this eventuality, and with reason.

I have applied a great many Whitman plates to the feet of elderly patients and believe that many of the criticisms of this form of support are due to the lack of that careful judgment that should be exercised in the selection of the case for an arch-prop that is mechanically perfect, yet rigid and unyielding. The metal insole of the old-fashioned shoe-store variety, has a limited field of usefulness; when it is used in conjunction with a shoe, built up on the inner side, it is comfortable, efficient, and to be recommended in the event of dropsy from cardiac or renal disease.

Gymnastics play an important rôle in the management of old patients with painful ankle and tarsal trouble; a flat-foot exerciser affords much comfort to sufferers from the arthritic complications. After a 15-minute use of the foot-circumduction machine there is experienced a new feeling of strength and added confidence in the feet. The exercises should be followed by skilfully administered massage, and kneading of the muscles of the sole, the tendons about the ankle, and the calf is of much benefit. Resistance movements and manipulation tend to strengthen the arch-raising muscles and to restore the normal range of motion. In some patients, experience is the only guide to answering the question as to whether or not adhesions are to be forcibly broken up. Occasionally this very breaking up may result in increased stiffness from intracapsular hemorrhage. The influence of a logical working diagnosis at the outset of treatment will determine a successful outcome.

It is surprising to note the widening list of the infecting ports of entry that may furnish the starting point for the polyarticular diseases that cripple so many old people. The teeth have been written upon to great length by many observers in the past few years. Some miraculous cases can be related following radical removal of infective oral foci. I have recently had under my care a woman of 55, who had been unable to walk on account of an infective osteoarthritis of the ankles and tarsus. She had been subjected to several operative procedures for the relief of the pain in her stiff, flat feet; plates were not tolerated. Her oral cavity was cleaned by the wholesale extraction of abscessed teeth, and she was very promptly enabled to walk. Another patient had suffered from a most severe septic form of articular rheumatism, frequently recurring; the trouble ceased when an abscessed bicuspid was drawn. The sources for infection are more numerous in older patients because resistance is lowered; thus we see in them more virulent types of chronic joint affection. I have seen several cases of polyarthritis in old men, traceable to a chronic cystitis. Besides the ear we must not overlook the accessory sinuses of the nose. Chronic infections of the gastrointestinal canal are often the cause of arthritis deformans.

The administration of medical adjuvants to mechanical treatment is not to be omitted when a case of intractable ankle arthritis complicates a flat-foot; tonics, thymus extract, pituitary extract, and even colchicum, should be employed in appropriate cases. For women at the climacteric I often use thyroid extract, as recommended by the French writers. Hot saline baths and spa treatment have their devotees. The Bier artificial hyperemia or dry hot-air baking is exceedingly beneficial as a pain-relieving measure in the chronically stiff and aching feet following subacute rheumatism in older subjects. The procedure requires time and careful attention to details, but the end often justifies the means. A household substitute is the alternating hot and cold foot douche.

Many flat-feet in older patients are not painful. We see many cases of "kidney feet" and "splay feet," which are the result of rickets in childhood. The flat-foot of adolescence, sometimes attributed to juvenile or adolescent rickets, is a more painful proposition. In the true rachitic flat-feet, even though much distorted, we find the joints accommodating themselves to altered functions, and such feet can bear their owners down the paths of life without any symptoms and without any arch props.

Corns and calluses are common after middle life,

even in normal feet; it is not necessary to point out the fact that a flat-foot encased in American shoes of the prevailing mode is sure to acquire these adornments if worn long enough. The busy family doctor is prone to decree plate-wearing for such clients. Corn-paring would prove more pain-sparing. Sometimes the chiropodists can do more and gain more friends than the careless general surgeon.

Metatarsalgia is very common in old people, but the number of cases in which this affection can be traced to flat-foot is in the minority. A great number of painful neuralgic cramps of the toes and the forefoot, in the absence of bunions or other distortions, are early symptoms of toxic or diabetic neuritis. Many ills of this sort are sadly neglected. After the diagnosis has been made and the patient placed under the care of his family physician, diabetic metatarsalgia requires a protective strip in the sole of the shoe, called by Cook the "anterior heel." The weight of the body is shifted, by this little device, backward to the less painful area of the plantar muscles.

Other obstinate and annoying forms of metatarsalgia are due to cerebrospinal disease. The blood-vessels, too, give out, in the wear and tear of life; obliteration and thrombosis are frequent in the declining years, inducing very painful interference with locomotion. The diagnosis and management of the various forms of angeitis need not be discussed here; but a plea for their early recognition is always timely. Almost every case of senile gangrene from localized arteriosclerosis that has come under my observation has been previously treated for something else.

Old patients cannot always stand a plate for the treatment of metatarsalgia, that we find so useful in the case of younger persons. Felt pads, strapped to the under surface of the ball of the foot are very much easier to tolerate. The shoemaker may line the shoes with the same soft material. Physical agents, such as massage, manual or even vibratory, are to be recommended. A few cases have improved with diathermia.

No type of patients discard the wearing of plates so quickly as those who have tried them in the presence of spurs of the os calcis. When these exostoses begin to torment by pain at the bottom of the heel (the condition seems to be more common in elderly women), their owners are soon forced to the conviction that the plates they have bought are provoking unbearable pressure on a painful spot. The logical treatment of a calcaneal painful spur is removal; yet conditions do not always warrant an operative procedure. I am inclined to believe that some of my patients suffering from these senile deposits have been relieved by baking; some are better off in the country, where they can walk on soft turf. There is no doubt that a small number of genuine exostoses on the under surface of the heel lose their senstiveness after the lapse of years; some of the elderly patients whom I have observed seem to be able to pursue their duties in the presence of demonstrably large bony spicules, which had been very painful during an earlier period.

People often wonder why their shoes become painful after fifty, even though the size, shape, last, and material are the same that they have been accustomed to for years. Occasionally this condition is felt most over the base of the fifth metatarsal bone. At this time of life the foot becomes more spare, fat that has protected bony surfaces before commences to atrophy, and the shoe may easily exert painful pressure. Sometimes an exquisitely tender bursa develops; careful shoe construction can, however, readily obviate these ills. It is often necessary to change the last of the shoe from time to time. It has been stated in articles on senility that one of the effects of old age is a "dropping of the arches"; that the old man's foot becomes flat as a result of universal muscular atrophy and weakening. I have examined many feet with this in mind and have come to an opposite clinical conclusion, as many, if not most, seem to present a heightened or raised form of arch; and whereas many of the plantar tissues atrophy after fifty, I firmly believe that nature makes ample provision against the so-called flat-foot of senility. She seems to provide for an increase of the normal turned-in position of the foot. Time and again I have been able to detect a slight tendency to bowing of the legs and actual outcurving of previously straight shins has not been rare. The same can be noticed in the works of some of our notable sculptors, Rodin, for instance.

Old people should have carefully fitted shoes and the only last that fills all requirements is that of an orthopedic shoe. Scrupulous attention to detail in fitting and selecting these will be found the best preventative against corns, bunions, and hammer-toes. Old people are prone to chilblains and frost-bite; the stockings should be of thick wool in winter and thin cashmere in summer.

Nacher says: "A serious difficulty in the treatment of old age is the uncertainty of the action of drugs on the senile organism. So little is known of the therapeutic action of drugs upon diseased, degenerating tissue. Drugs which are almost specifics in certain diseases in maturity may be ineffectual in similar conditions in senility." Surgical and hygenic measures, however, as well as orthopedic efforts, offer much hopeful result if judiciously planned and carefully carried out.

15 West Forty-fourth Street.

CARDIAC CRISES IN TABES DORSALIS.

REPORT OF A CASE WITH SUDDEN DEATH.

By MAURICE F. LAUTMAN, M.D.,
HOT SPRINGS, ARK.
MEDICAL DIRECTOR, LEO N. LEVI MEMORIAL HOSPITAL.

Specific involvement of the sensory functions of the pneumogastric nerves or sympathetic nervous system in different locations is said to be the cause of attacks of pain in the various organs, which are known as visceral crises.

These crises are quite characteristic and easily recognized, especially if an existing tabes has been established as the etiological factor, and most frequently involve the gastrointestinal tract. In addition to the gastric, intestinal, and rectal, crises have also been known to occur in the nose, larynx, liver, kidney, bladder, urethra, and clitoris.*

Attacks of pain about the heart in tabes are not uncommon. These have usually been described as girdle sensations, although real anginoid attacks are occasionally encountered. True cardiac crises, however, are extremely uncommon; in fact, their existence as a manifestation of tabes is a matter of dispute.

*I have under observation at present a young tabetic with testicular crises which, like all tabetic pains are aggravated, temporarily, following intraspinous treatment.

Osler[1] refers to cardiac crises, because he has seen them in several cases, but inasmuch as these patients were at an age when true angina pectoris could not be excluded, their exact value as a symptom of tabes had to be questioned. Starr[2] says that cardiac crises may occur in tabes, but they are extremely rare; he has never seen a case. Gaucher[3] seems quite certain that cardiac crises do occur, and emphasizes the need of distinguishing them from the rapidly curable syphilitic angina pectoris. Massary[4] is of the same opinion, and quotes Heitz,[5] who found in tabetics a degeneration of the medullated fibers of the cardiac plexus.

The case to be reported occurred in a man (E. D. No. 225), 46 years old, who had an initial lesion followed by a rash twenty years ago. He had had no constitutional treatment whatever, and felt in excellent health until two years ago, at which time he began to have nocturnal headaches and double vision. Since that time there have developed sexual impotence, shooting pains in legs, rectal and vesical incontinence, numbness and tingling in the legs, and failing memory.

He has noticed difficulty in pronouncing his words of late. There has been an aggravation of all his symptoms for the past eight months, since which time he has been walking with crutches. He complains of a constricting band sensation about two inches wide encircling his body at the free costal margin and for the past eight months he has had attacks of pain over the heart. These pains come on quite suddenly, are stabbing in character, and radiate up into the neck. The pain is very severe while it lasts, the heart "seems to stop beating," but the attack usually disappears about five minutes after reaching its maximum intensity.

On physical examination the patient was seen to be poorly nourished and developed. The pupils were widely dilated, irregular, unequal, the right larger than the left, and did not react to light. There was a marked tremor of the face and tongue with dysarthria. The lungs were clear, and no abnormalities could be made out in the heart except a slight accentuation of the second aortic sound. The abdomen and abdominal viscera were negative. The gait was typically tabetic, and pronounced inco-ordination and Romberg sign were present; all the deep reflexes were abolished. The systolic blood pressure was 130; the diastolic 94.

The Wassermann blood reaction was two plus, and the spinal fluid, which contained 121 cells per cmm. and three plus globulin, gave a four plus inhibition with 0.05 cc.

Four days prior to his death he received an intraspinous injections of mercury in his own serum from which he had very little discomfort, only slight pain, and the maximum temperature following the treatment was 99.6°. He recovered very quickly and two days following the injection felt quite well, was walking about as usual, and remarked that the pains about the heart were not so severe. He appeared as well as ever on the morning of his death, when suddenly while sitting on the bed, talking to a patient, he uttered a cry, clutched at his heart, and fell back on the bed. He was seen about a minute later and was pulseless; stimulation failed to revive him.

Postmortem Examination: The pericardial fluid was increased in amount, the heart had stopped in systole and showed moderate hypertrophy. It weighed 305 grams; the left ventricle was 2.1 cm. thick, the right 0.8 cm. The valves, as well as the coronary arteries throughout their entire extent, showed no abnormalties. The aorta, with the exception of three small atheromatous, calcified plaques on the posterior wall, just above the ring, was negative. In addition, the capsule of the liver showed a few cicatrices, there was a Meckel's diverticulum, and there were only two lobes in the right as well as the left lung.

Summary and Conclusions.—In a man with advanced taboparesis there occurred attacks of pain about the heart, in the nature of cardiac crises. There were no postmortem evidences to explain the sudden death which occurred in one of the paroxysms, which renders quite plausible the assumption that death was due to a cardiac crisis.

LATE INFECTION FOLLOWING THE CORNEOSCLERAL TREPHINE OPERATION FOR GLAUCOMA.

By CHAS. B. BRODER, A.B., M.D.,

NEW YORK.

INSTRUCTOR IN LARYNGOLOGY, POLYCLINIC MEDICAL SCHOOL, ADJ. OTOLARYNGOLOGIST, CITY HOSPITAL; VISITING OPHTHALMOLOGIST AND OTOLOGIST, PEOPLE'S HOSPITAL.

THE trephine operation for glaucoma by its simplicity of technique and by its immediate favorable results has appealed strongly to the average oculist and has now become a well established operative measure.

It is now about five years since Col. Elliot introduced the operation and since then it has been practised extensively throughout the medical world. In the enthusiasm of the moment and in the eagerness of the profession to grasp at a procedure that will cure or at least retard the course of some forms of glaucoma not helped by an iridectomy, the secondary and remote dangers resulting from this new method have been overlooked.

Lately two cases of late infection of unusual severity following the scleral trephine operations have been seen by the writer.

CASE I.—J. S., thirty-five years of age, was first seen by me March, 1915, when he came to have his glasses for reading changed. Examination showed evidence of a trephine operation combined with an iridectomy in each eye, which had been performed three years previously. The left eye had very little vision, hand movements at five feet. The nerve was pale, atrophic, and there was a deep depression. There was no increase of tension. In the right eye vision was 20/30 with correction plus 1.00 spherical. Disc slightly cupped. Tension 22 mm. Hg.

The patient was not again seen by me until April 15, 1916, when he came to my office and said that while working at his trade some aniline pigment got into his right eye and he rubbed it to allay the irritation. He awoke the next morning with the lids stuck together, and the eye inflamed and painful. On examination the eyeball was deeply congested and over the trephine opening was a raised and circumscribed yellowish mass. There was a distinct exudate in the anterior chamber. The upper part of the cornea near the flap showed a superficial ulceration and the rest of the cornea was dull. The fundus could not be seen. Vision was reduced to light perception and tension was normal. Under treatment the hypopyon gradually disappeared and the cornea cleared up, revealing an active iridocyclitis with opacities in the vitreous and deposits in the pupillary area and around the lens.

The patient was kept in the hospital for seven weeks and the inflammation slowly abated. At present, vision is greatly reduced (5/200) on account of the floating vitreous opacities and the altered condition of the lens.

The intraocular inflammation in this case was evidently secondary to the corneal ulcer, the infection involving the conjunctival flap and spreading to the ciliary body through the scleral opening.

CASE II.—M. R., fifty-two years old, was first seen by me June 15, 1916, and gave a history that the left eye had been enucleated three years ago following two operations for glaucoma, and the right eye had been operated on shortly after for the same disease with the preservation of good vision. Three days before his next visit, the remaining eye suddenly became painful and red and the vision foggy. An examination showed an acute conjunctivitis with infection of the in-

terior of the eye. The site of the flap over the trephine opening was obscured by a yellowish elevated bleb. Hypopyon was present. Signs of a severe iridocyclitis were visible, fibrinous deposits in the pupillary area, and on the surface of the lens capsule and opacities in the vitreous. Very little vision was present. The infiltrate in the anterior chamber disappeared in a few days, but the infection of the conjunctiva and ciliary body was obstinate and persisted for several weeks in spite of rigid treatment.

At the time of discharge from the hospital, the inflammation had subsided, but the vision, due to the iritic deposits on the lens and the vitreous opacities, was greatly reduced, the patient being barely able to find his way about.

The unfortunate outcome in these two cases, the infection in each instance involving the remaining good eye and leading almost to total loss of vision, together with the increasing number of cases being reported of secondary complications following the trephine operation for glaucoma, should teach us to be guided in our prognosis concerning the ultimate outcome, and to use this method of procedure only as a last resort.

Besides late infection other pathological conditions following the trephine operation have been reported, such as opacification of the lens, and closure of the trephine hole by proliferation of connective tissue, or by being blocked by iris, ciliary body, suspensory ligament or lens. In acute and subacute glaucoma the consensus of opinion seems to favor the ordinary iridectomy as the operation of choice. In glaucoma simplex, the miotic treatment should be persisted in as long as the intraocular pressure is controlled, and the visual field and central vision are not on the decline. A majority of these cases will yield to therapeutic measures.

In those cases of chronic glaucoma that are uninfluenced by miotic and constitutional treatment, and operative measures are essential to save the sight, a broad iridectomy properly executed will often stay the course and should first be tried, offering as it does more rapid healing and lessened liability to infection.

In some cases an iridectomy will fail to control the symptoms, on account of far advanced structural changes in the filtration area, in which event the trephine operation is the only choice open, and it should then be performed over the site of the coloboma. As a possible prevention against subsequent infection, the conjunctival flap should be made as large as possible and quite thick.

221 Second Avenue.

Treatment of Auricular Fibrillation.—Robert H. Babcock states that there are three principal indications in the treatment of this affection in addition to rest in bed. First, the relief of insomnia and dyspnea, which is almost always afforded by hypodermics of morphia. One injection should be given each evening with an attempt to reduce the dosage. If morphin fails for any reason, heroin or codein may be employed. Second, the relief of visceral congestion, which is accomplished by the use of purgatives which are secondarily indicated to antagonize the action of morphin. An alkaline purgative on waking each morning should follow an initial catharsis on the first evening of treatment; the author prefers blue mass, 5 grains, for this purpose, combined with a saline and a little hyoscyamus. The patient should have two or three watery evacuations daily. The third indication—which may not always be present—is cardiac stimulation. In all severe cases, and sooner or later in all cases, digitalis will be called for. At the outset the Karell diet is recommended. Under this management some compensation may return, perhaps with ability to resume occupation in some measure. This may require the daily use of digitalis, and the patient in any case should be under constant supervision.—*The Medical Herald.*

Medicolegal Notes.

Privileged Communications.—In a servant's action for injuries, where defendant compelled plaintiff to give testimony as to his statement to a hospital physician regarding his injury, by recalling him to the stand and exacting a statement that he had told the doctor at the hospital how long he had had pain and when it first started, the New York Appellate Division held that plaintiff did not waive his privilege covering his statement to the hospital physician.—Murphy v. New York, N. H. & H. R. R. Co., 157 N. Y. Supp. 962.

Physicians Need Not Keep Records of Prescriptions for Dangerous Drugs under New York Statute.—Under section 248 of the New York Public Health Law, as added by Laws 1914, c. 363, and amended by Laws 1915, c. 327, providing that all persons authorized by law to handle dangerous drugs shall keep certain records of such drugs when "dispensed, given away or in any manner delivered," and declaring a violation of the section a misdmeanor, and section 246, forbidding the delivery of such drugs without a physician's prescription, and providing for records of such delivery, a physician who wrote prescriptions for dangerous drugs without keeping a record of the transactions was not guilty of a violation of section 248, as he did not "dispense" the drugs himself; the statute making a distinction between the "dispenser" of the drugs and the physician who writes the prescription.—People v. Cohen, 157 N. Y. Supp. 591.

Punishment for Practising Without License.—Texas Penal Code 1911, Art. 756, provides that the punishment for unlawfully practising medicine shall be by fine of not less than $50 nor more than $500, and by imprisonment for not exceeding six months. A conviction was had and punishment assessed at a fine of $100. On appeal this was reversed. On conviction the jury must assess both a fine and imprisonment within the legally fixed maximum and minimum.—Rutherford v. State, Texas Civil Appeals, 187 S. W. 481.

Treating Patient with Cocaine.—In an action against a physician for selling cocaine there was evidence that the person to whom the drug was sold, though addicted to the use of it, was suffering from a disease for which cocaine was a known remedy, and that the defendant sold him the drug as a treatment for it. It was held that the Missouri statute making it unlawful for any druggist or other person to retail or sell or give away cocaine except on the written prescription of a licensed physician or dentist was not intended to cover cases of a physician selling and delivering cocaine in the course of his practice and in his treatment of a patient.—State v. Hesse (Mo.) 187 S. W. 571.

Waiver of Privileged Communications.—The Missouri statute makes physicians incompetent witnesses as to any information acquired from a patient, which was necessary to enable them to prescribe. This statutory provision is in derogation of the common law and creates a privilege which the patient may waive at will. In an action for personal injuries the plaintiff, as a part of his case, stated the advice given to him by his attending physician as to his physical condition and future fitness for work at the time he left the hospital. This, the Missouri Supreme Court held, opened the door for a full inquiry as to the knowledge of the physician of the health and extent of the injuries of the plaintiff at the time of the alleged statement by the physician, and as to what advice he then gave the plaintiff in view of the knowledge on which it was predicted.—Blankenbaker v. St. Louis & S. F. K Co. (Mo.) 187 S. W. 840.

Liability for Services to Minor Child.—In an action by a physician against a married woman for services to her minor child, living with her, it appeared that she and her husband, the father of the child, lived together. The Texas Court of Civil Appeals held that in order to make the wife personally liable for the services, she must have entered into a contract therefor. Her mere acquiescence or consent for the doctor to treat her child would not bind her personally or make her separate estate liable. It is not sufficient that she merely give an order or call in the physician, for in such case the presumption is that she does so as the agent of her husband, whose duty it is to supply such things. After the services were rendered a mere verbal promise on her part to pay would not render her separate estate liable for the debt of the community. She would not be bound personally for the default of her husband by such verbal promise to pay his debt.—Davenport v. Rutledge (Tex.) 187 S. W. 988.

THE VALUE OF THE MEDICAL RESERVE CORPS.

IT has not been so long that the Medical Reserve Corps was regarded as something of a farce by the civilian practitioner on one hand and the military surgeon on the other. It was the custom to allude to one's appointment as first lieutenant in that body in the speech after the medical banquet, in a facetious vein, as being a rather good joke on the army. Despite this playful attitude toward such a commission there have always been title-loving physicians who were not at all averse to adding it to their names as they appeared on publications; these were usually the ones who were especially prolific with printed matter. The designation of the original appointments to the Reserve Corps as the "Distinguished List" served to animate the fiction that the possessor of one of these commissions had received a sort of honorary degree, in recognition possibly of his superior attainments.

The Spanish-American War probably did more to wake up the profession to a realization of its responsibility to the country in the matter of military medicine than any other event. It is a matter of history now, and history that does not make pleasant repetition, how the few trained military surgeons were overwhelmed by an avalanche of civilian physicians, ignorant of tactics, transportation, administration, in fact every branch of military medicine. There were six of these untrained doctors to every trained surgeon in that war. That there has been a great improvement in this regard has been shown by the prompt response of the surgeons of the Reserve Corps to the country's need during our recent border trouble. At present there are more than 250 reserve officers now on regular duty. To quote Lieutenant-Colonel L. Munson, M. C., U. S. A., editor of the *Military Surgeon*, "All of these are selected men, many of them with a good theoretical knowledge of the special duties of the medico-military officer and not one without, at least, a conviction that there are such special duties, with good reasons for their existence."

The question of rank has often obscured the real issue in the minds of some. We recall one practitioner, known as one of the most successful in a large city and professor of practice of medicine in a large college, who related at a medical banquet his experience at the time of the occupation of Vera Cruz. He held a commission as first lieutenant in the Medical Reserve Corps, and went to see an officer in the Medical Corps with some idea of offering his service. "But," he said, "when I found that I would be subject to orders from some youngster of twenty-odd years old whom I had quizzed in my classes I promptly resigned my commission." This specimen of patriotic ideals was related in a humorous way and was greeted with more or less laughter. In pleasing contrast to this attitude, let us quote a sentence here and there from a speech by First Lieutenant Henry C. Coe of the Reserve Corps before an annual meeting of the Association of Military Surgeons (*Military Surgeon*, September, 1916): "We have been presented with the honorable title of lieutenant in the regular service, for which regular officers have worked. We owe it to the Government to earn our right to the office and its privileges. . . . The members should not lie awake nights to think how they can add another bar, or a leaf, or a spread eagle to their shoulder straps. We are all doctors, thank God, as we are all officers and gentlemen. If there is any nobler title than this, I don't know it. The youngster with the double hurdle is my superior officer, and as such I expect to obey him promptly as if he were the chief surgeon. Envy, distrust, self-importance —these have no place in our corps."

This surely expresses the attitude of our profession toward our country. If we join the Medical Reserve Corps let us do it with no mental reservations, but with a whole-hearted intention to give the best that is in us to our country, to make that gift valuable by preparation in time of peace and self-abnegation in time of war.

THE DECLINING BIRTH RATE OF GREAT BRITAIN.

A DECLINING birth rate is generally regarded as an index of decadence of a race or nation. This view, however, is by no means universal among prominent scientists, for many hold to the Malthusian opinions that it is better to have a well selected population and one of a general high standard than a larger but more mixed and, on the whole, inferior class. Nevertheless the majority of individuals still adhere to the Bible admonition "be fruitful and multiply" and to other ethical principles as "do not attempt to outwit nature," and "the public interest demands a high birth rate, private selfishness desires a small family."

It is instructive to turn to the British birth-rate commission's report published recently, dealing with statistical evidence on the matter. The commission has found itself warranted in concluding that in Great Britain, as in other countries of Northern and Western Europe, there is unmistakable proof that a sharp decline is taking place in the birth rate, and there seems no reasonable ground for doubting that the countries included will ultimately reach the state of France. The birth-rate in England and Wales has declined approximately to the extent of one-third in the past thirty-five years. Statistics seem also to show that in the countries such as France in which the decline first

showed itself the downward progress has been slow, while in those in which it has been recent, such as Germany, the fall has been more precipitate. It would seem as if in the statistical part of the report the commission had tried to find other causes than artificial restraint to account sufficiently for the decline in the birth-rate. Nevertheless, the conclusion was borne in upon them that the fall was not due, at any rate to any important extent, to alterations in the marriage rate, to a rise of the mean age of marriage, or to other causes diminishing the proportion of married women of fertile age in the population. Density of population was insufficient to explain it, for the rural rate was not widely different from the urban; food might exert some influence, but it would be difficult to get facts and figures of any value in support of this view. The theory of cyclical variations in the natural power to conceive or procreate, the hypothesis of variability of germinal vitality, as brought forward by Dr. Chalmers of Glasgow and others, was very attractive, but it broke down in the face of Irish figures. The commission was also compelled to give up the view that the higher education of women had any bearing on the decline. Statistics appear to show that there is no physiological difference between the fertility of college and non-college women, although there surely must be a slight difference in the probability of offspring being brought into the world owing to the later age at which women educated at college, must of necessity, marry.

In short, while the commission was unable to discover any sufficient cause for the falling rate, beyond that of conscious limitation and artificial restraint, yet certain circumstances did affect fertility, and brought it about that the decline must be regarded as dysgenic and not eugenic. The fall in the birth-rate in England and Wales had been more marked in those districts in which a higher standard of living was found; the size of the family tended to vary inversely as the social status of the parents, professional and allied occupations having a low fertility and laboring occupations generally a high one (that of coal miners being very nearly twice that of physicians). Housing conditions, too, had an influence, for fertility decreased regularly as the size of the tenement increased, and infantile mortality decreased along with it, but the saving of infant life in more commodious and comfortable tenements compensated, to a slight extent, for the lower fertility of those living in them.

Thus it cannot be denied that fertility is closely connected with social status, the relation being such that the more prosperous the social class the lower the fertility. Moreover there is no proof that the higher mortality among the infants of the lower social class suffices to adjust the difference. Consequently the decline cannot be regarded as eugenic, but is out and out dysgenic. That is to say that the babies are not fewer and of a superior quality but the contrary. It may be for the good of a nation if babies are fewer and of a finer quality, but when they are fewer and of an inferior quality it is obviously and distinctly detrimental.

Three suggestions are made, for which the medical part of the commission is presumably responsible. The first is that women should be assured that the pains of child bearing can be mitigated. The second suggestion calls for an increased knowledge with regard to the ways in which quality as well as quantity may appear in the expected babies. The third suggestion is that infantile and child mortality should be checked by means taken not only after but before birth, that is, by a maternity and child welfare scheme. Decrease of birth rate appears invariably to go hand in hand with civilization, and the more advanced the civilization the greater the decrease of birth-rate. France is probably, regarded from all standpoints, the nation most advanced in civilization, and it is in France that the birth-rate is the lowest.

A PLEA FOR THE HOSPITAL INTERNE.

THE hospital interne occupies an exalted or a subordinate position, depending on the point of view. To the young nurses and orderlies he is more or less of a little tin god—to the visiting staff a useful adjunct or a necessary nuisance, according to the personal equation involved. Possibly he (with increasing frequency in these enlightened times—she) is a more important part of the hospital machinery than is realized. He occupies an intermediate position between the hospital management and the visiting staff on one side and the nursing staff on the other. He learns from the one and teaches the other.

In an article in the *Southern Hospital Record* for July, Dr. Emory Park speaks a few words on behalf of the resident physician or interne. Some of his statements should be quoted and applauded: "The hospital shouldn't demand that the interne write all the histories and do the other detail work and then step aside when the operations are performed and let some outsider be the assistant at the operation." "Some hospitals let inconsiderate members of their visiting staff call residents away from their meals or let them set their operations at that time as will make the interne either miss a meal or choke it down in hunks." "They should be well fed and provided with clean, comfortable rooms and bathrooms."

Internes seldom receive any money except in some instances a nominal sum. The tacit arrangement in vogue is in the nature of a fair exchange. The hospital receives service which is in reality indispensable; each patient is visited once, twice, or more times a day, routine dressings are done and the feeling is that the patients are protected—that there is for twenty-four hours a day a staff of trained men on guard, capable of interpreting symptoms and knowing when to call in the more experienced physicians. They may be likened indeed to the outposts of an army camp. They recognize danger at a distance, and it can be repulsed before it threatens the heart of the army itself; so that the general sleeps more soundly in his tent, just as the famous surgeon is able now and then to take a week-end knowing that Smith and Jones at the hospital will not have him called needlessly, but also that they will not let any of his patients die for want of attendance. In return for these services the interne expects and should receive ex-

perience. Not the facility of inscribing "Mag. sulph. ℥i" in an order book until he wakes from dreams writing it in the air, not the holding of the surgeon's coat while he puts on a plaster cast, and not the bird's-eye view of the operation as third assistant, but the actual diagnosis and treatment of cases, the administration of anesthetics, and the performance of operations. For each interne in his hospital each member of the visiting staff should feel the kindly interest which the old-time preceptor had for his pupil.

We do not favor the loosing of a recent graduate, full of theory, but deficient in practice, upon wards of helpless sufferers. But certainly the interne should have free scope with his stethoscope in the wards, and he should be allowed to give anesthetics, at first under supervision, but later alone, and there is no reason why he should not be first assistant at operations and even do a large part of them himself.

Many hospitals and diverse ideals of management pass before our eyes as the years go by. We have seen hospitals where anesthetists were called in from the outside to serve in rotation to the exclusion of the resident staff, where each surgeon seemed to have always some protégé whom he brought into operations to act as first assistant while the interne who had examined the case, prepared it for operation, and would later carry it through the miseries of the postoperative period, stood around and passed instruments. We have seen hospitals where the tip went forth to potential candidates that the food was bad, thus frightening away many a good man. Another one where the doctors' home consisted of a ramshackle frame building, which prospective internes took one look at and fled. As Dr. Park reminds us in his article, the hospital interne is not only a highly and specially educated person, but he is a gentleman. He is entitled to the treatment accorded a gentleman anywhere and, in addition, to the full amount of the consideration for which he gives his services, that is, all the experience which the hospital affords together with the advice and oversight of the older men attached to the staff. The hospital period is probably the most valuable of the young doctor's training if he is fortunate enough to get in the right sort of a hospital, and with a little friendly cooperation by those responsible for the management of the hospitals all of them would be made desirable in this regard.

The Rationale and Practice of Chemotherapy.

Our notions of chemotherapy are at present in an unsettled state, for we do not know how many forms of therapeutic activity are to be comprised under this term, nor, so far as we have gone, are we sure in practice even of the parasitotropic action of arsenic in infectious diseases, and chiefly of salvarsan in syphilis. J. E. R. McDonagh believes that salvarsan is not truly parasitotropic, because it attacks only a certain formation contained in the spirochete by reason of an oxidizing action. Salvarsan is on the other hand organotropic and toxic and attacks especially some of the intracranial tissues. Much of McDonagh's reasoning is directed against Ehrlich's side-chain theory which takes for granted that chemotherapy is parasitotropic therapy. On the other hand McDonagh may be correct in his belief that chemotherapy is a matter of oxidations and reductions. He has used non-toxic oxidizing compounds of sulphur or iron in an attempt to replace arsenic, but evidence of cure of obstinate syphilitic lesions by such drugs is not yet regarded as entirely conclusive. Dr. C. H. Browning has claimed that chemotherapy really began thirty years ago with the use of methylene blue, a sulphurated compound, in malaria. Mr. John Ward holds that a parasitotropic substance must be organotropic as well. Arsenic, which in certain combinations is the most powerful parasiticide, is also highly organotropic, hence toxic. Iron is neither parasitotropic nor organotropic, while sulphur, non-parasitotropic, is organotropic in that it is a stimulant to organic cells and tissues. McDonagh first passed from toxic arsenic to its congener phosphorus, but finding this likewise too toxic, made experiments with a third metalloid, sulphur, which he incorporated into certain synthetics closely resembling in composition salvarsan. Intramine, one of these, has been used somewhat since the war began as a substitute for salvarsan but is admittedly inferior to the latter save, it is alleged, in recurrences. McDonagh insists, however, that with it should be associated for best results a reducing principle, namely colloidal iodine, to be introduced into a vein or muscle. McDonagh has also prepared a synthetic of the salvarsan type in which iron enters. He insists especially on the value of intramine in intracranial syphilis which is often made worse by salvarsan; also in so-called neurorecidives which salvarsan has been accused of causing.

Synesthesialgia.

This term is used by some neurologists as a condensation of synesthesia algica, a rare phenomenon encountered in lesions of the median and sciatic nerves, in which there is pain referred to the hand or foot which is not in the area of distribution of the affected nerve, and has no relation to the ordinary neuralgic or neuritic pains proper to the nerve trunks themselves. Weir-Mitchell associated certain pains (causalgia) with areas of glossy skin and ascribed both to the presence of a neuritis. Meige and Benisty referred this sympathetic pain to a vascular component—alterations in the blood-vessels. Leriche believed that both pain and trophic changes (glossy skin) were due to inflammation of the sympathetic fibers. Souques suggested the operation of a reflex mechanism. An article in the *Rivista Critica di Clinica Medica* for August 12 calls attention to some recent work in this field by Micheli who reported two cases of causalgia from nerve injury associated with synesthesialgia. The former symptoms could be ascribed to vasomotor and trophic alterations which occur in specially disposed individuals, viz., those with increased vasomotor excitability. Stimuli proceeding from these areas make themselves felt on sound portions of the skin. The patients always seek to relieve the burning pain of causalgia with moist applications, hence the parts become macerated. Micheli places a rubber glove or sock on the affected hand or foot, and in this way protects the surface from outside irritation. Leriche reports a sympathectomy or resection of the perivascular sheaths for a length of 8 or 10 cm., which has given him good results.

News of the Week.

Army Medical Corps Examination.—The Surgeon General of the Army announces that a preliminary examination for appointment of first lieutenants in the Army Medical Corps will be held early in January, 1917, at points to be hereafter designated. Full information concerning the examination can be procured upon application to the "Surgeon General, U. S. Army, Washington, D. C." The essential requirements are that the applicant be a citizen of the United States, between 22 and 32 years of age, graduate of a recognized medical school, and of good moral character and habits, and have had at least one year's hospital training, as an interne, after graduation. In order that all arrangements for the examination may be perfected, applications should be forwarded without delay to the Surgeon General of the Army. There are at present 228 vacancies in the medical corps.

The Western Surgical Association will hold its next session on December 15 and 16 at St. Paul, Minn., instead of at Indianapolis as scheduled. The change has been made because of the absence of the chairman of the committee of arrangements, Dr. Joseph Rilus Eastman of Indianapolis, who is "somewhere in Austria" at the head of a surgical unit.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga prize, amounting to $250, will be made on July 14, 1917, provided that an essay deemed by the committee on award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but must not have been published. They must be typewritten, in English or accompanied by a translation, and must be in the hands of the secretary of the college on or before May 1, 1917. Further particulars may be obtained from Dr. Francis R. Packard, secretary, College of Physicians, 19 South Twenty-second Street, Philadelphia.

Dr. Bulkley's Lectures.—The governors of the New York Skin and Cancer Hospital announce that Dr. L. Duncan Bulkley, assisted by the attending staff, will give the eighteenth series of Clinical Lectures on Diseases of the Skin, in the Out-Patient Hall of the hospital, on Wednesday afternoons, beginning November 1, 1916, at 4.15 o'clock. The lectures will be free to the medical profession on the presentation of their professional cards.

Paratyphoid Carriers.—Forty-five members of the 14th and 71st Regiments, just returned from the border, are carriers of the paratyphoid bacillus, according to examinations made by the Health Department. The 14th, which had 130 cases of the disease, furnished forty healthy carriers, and the 71st, with fourteen cases, turned out five carriers.

Infantile Paralysis in New Jersey Institutions.—A member of the freshman class at Princeton University died last Saturday from poliomyelitis, and a case of the disease has been reported at the State Normal School in Trenton.

Tin Sickness (?) in Germany.—The Amsterdam correspondent of the *Exchange Telegraph* in London says that "a remarkable disease is spreading in many parts of Germany, especially in Berlin, Hamburg, Munich, and Cologne, caused by continual feeding from preserved foods. The sickness is described as 'tin sickness.' It is considered a serious form of blood poison. Thousands of cases are reported in every large city, although the authorities exercise strict control over the tin used for preserved foods." If the story is true, it is more likely that the trouble is a deficiency disease, canned foods being notably lacking in vitamines.

American Ambulances for Balkans.—The recently formed section of the American Ambulance Field Service, which is to be attached to the French Army in the Balkans, left Paris on October 13 for Saloniki.

To Attack Christian Science.—The New York County Medical Society, through the Comitia Minora, has determined to conduct a State-wide campaign for the elimination from the public health law of that section under which, by a recent ruling of the Court of Appeals, Christian Scientists may claim the right to practise.

Gifts to Charities.—Among a number of other charitable institutions the Brooklyn Home for Consumptives, Brooklyn, N. Y., receives a bequest of $5,000 under the will of the late Mrs. Albert Bierstadt of that city.

Harvey Lectures for 1916-1917.—The first lecture of the Harvey Society for the present season was given on October 14, at the New York Academy of Medicine, by Prof. J. S. Haldane of the University of Oxford on "The New Physiology." The other lectures of the series will be as follows: November 4, Dr. F. M. Allen, Hospital of the Rockefeller Institute, "The Role of Fat in Diabetes"; November 25, Dr. Paul A. Lewis, Henry Phipps Institute for Tuberculosis, "Chemo-Therapy in Tuberculosis"; December 16, Prof. Henry H. Donaldson, Wistar Institute of Anatomy and Biology, "Growth Changes in the Mammalian Nervous System"; January 13, Prof. E. V. McCollum, University of Wisconsin, "The Supplementary Dietary Relationships Among Our Natural Foodstuffs"; February 3, Prof. J. W. Jobling, Vanderbilt University, "The Influence of Non-specific Substances on Infections"; February 24, Prof. John R. Murlin, Cornell University, "The Metabolism of Mother and Offspring Before and After Parturition"; March 17, Prof. Francis W. Peabody, Harvard University, "Cardiac Dyspnea"; April 7, Prof. W. H. Howell, Johns Hopkins University, "The Coagulation of the Blood." As in the previous years, the lectures will be given on Saturday evenings at eight-thirty, at the Academy of Medicine, and will be open to the public.

Cartwright Lectures.—As previously announced the Cartwright lectures of the Association of the Alumni of the College of Physicians and Surgeons, New York, will be delivered by Prof. Richard M. Pearce of the University of Pennsylvania at the college, 437 West Fifty-ninth Street, on October 24 and 25, at 5 o'clock. The subject of the lectures will be "The Spleen in Its Relation to Blood Destruction and Regeneration."

X-ray Victims.—A dispatch from Paris states that Dr. Minard, radiologist at the Cochin Hospital, has been decorated with the Legion of Honor as a recompense for the loss of two fingers through exposure to the *x*-ray in the course of his work on wounded soldiers.

Dr. Francis LeRoy Satterlee of New York has recently undergone a third operation for the removal of a cancer of the right hand, the result of exposure to the *x*-ray some years ago.

Dr. Maynard Ladd of Boston has been appointed physician-in-chief of the children's department of the Boston Hospital and Dispensary, succeeding Dr. A. A. Howard.

College Opens.—The Medical School of Cincinnati University, Cincinnati, Ohio, opened on October 3, with an enrollment of 100 students, an increase of twelve over last year. Ten of the students are women.

Epidemic Waning.—The total record of the poliomyelitis epidemic in New York on October 14 was 9,202 cases and 2,352 deaths, the decline in the number of new cases having been marked during the week.

Mrs. Olive H. M. Rutherford, sixth vice-president of the National Society of Druggists, and said to have been the oldest pharmacist in this country, died at her home in Brooklyn on October 13, aged 85 years.

Rocky Mountain Spotted Fever in California.—Dr. Frank L. Kelly, assistant epidemiologist of the California State Board of Health, recently made an investigation in Modoc and Lassen counties, California, for the purpose of determining the prevalence and geographical distribution of Rocky Mountain spotted fever in those localities. He found that from 1903 to 1916 (the figures of the latter year being, of course, incomplete) 6 cases occurred in Modoc and 32 in Lassen County, the two counties being in the northeastern corner of the State and contiguous. Of these cases 11 occurred in Lassen County in 1915 and 8 in the first part of 1916. During 1915 Modoc County had no cases, and during the first part of 1916 two were reported. The total mortality among the 38 cases was 6. Dr. Kelly's conclusions are: 1. Rocky Mountain spotted fever has existed in California for a much longer period and to a far greater extent than has hitherto been supposed. 2. There are probably five main infected areas, one in Modoc County and four in Lassen. 3 The disease is not as severe in California as in Montana, nor as light as in Idaho. 4. The infection probably entered California through Nevada rather than Oregon.

Medical Society Elections.—Indiana State Medical Association: Annual meeting at Fort Wayne on September 28 and 29. Officers elected: *President*, Dr. John H. Oliver, Indianapolis; *Vice-presidents*, Dr. John W. Phares; Evansville; Dr. Charles M. Mix, Muncie, and Dr. George L. Guthrie, Indianapolis; *Secretary-Treasurer*, Dr. Charles N. Combs, Terre Haute.

Medical Society of the Missouri Valley: Annual meeting at Omaha, Neb., on September 22. Officers elected: *President*, Dr. Charles R. Woodson, St. Joseph, Mo.; *Vice-presidents*, Dr. E. W. Rowe, Lincoln, Neb., and Dr. C. B. Hickenlooper, Winterset, Ia.; *Secretary*, Dr. Charles W. Fassett, Kansas City, Mo.; *Treasurer*, Dr. Oliver C. Gebhart, St. Joseph, Mo.

Orleans County (Vt.) Medical Society: Annual meeting at St. Johnsbury on September 12. Officers elected: *President*, Dr. B. D. Longe, Newport; *Vice-president*, Dr. P. C. W. Templeton, Irasburg; *Secretary-Treasurer*, Dr. James F. Blanchard, Newport.

Burlington-Chittenden (Vt.) Clinical Society: Annual meeting at Burlington on Sept. 28. Officers elected: *President*, Dr. E. H. Buttles; *Vice-President*, Dr. Fred W. Sears; *Secretary-Treasurer*, Dr. O. N. Eastman, all of Burlington.

Obituary Notes.—Dr. Matthews Woods of Philadelphia, a graduate of the University of Pennsylvania, School of Medicine, Philadelphia, in 1873, and a member of the Medical Society of the State of Pennsylvania, the Philadelphia County Medical Society, the American Medical Association, and the Philadelphia Psychiatric Society, died in Philadelphia on October 14, aged 63 years.

Dr. George Carleton Dominick of New York, a graduate of the New York Homeopathic Medical College and Hospital, New York, in 1904, attending physician to the Metropolitan and Volunteer Hospitals, and a member of the American Institute of Homeopathy, the New York State Homeopathic Medical Society, and the Academy of Pathological Science, died at sea, from tuberculosis, after a long illness, on October 2, aged 39 years.

Dr. Tobias John Green of Mexico, N. Y., a graduate of the Geneva Medical College, Geneva, N. Y., in 1845, died suddenly at his home on October 4, aged 98 years.

Dr. Grace A. Murphy Curry of New York, a graduate of the Woman's Medical College of the New York Infirmary for Women and Children, New York, in 1897, formerly assistant pathologist at the City Hospital, Troy, N. Y., died suddenly on October 3, aged 47 years.

Dr. John Joseph Thompson of Webster, Mass., a graduate of Jefferson Medical College, Philadelphia, in 1887, and a member of the American Medical Association, the Massachusetts Medical Society, and the Worcester District Medical Society, and a trustee of the Webster School Board for nine years, died at his home after a long illness, on September 16, aged 56 years.

Dr. William D. Moore died at Philadelphia on September 28 at the age of 49 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1893, and was a member of the Medical Society of the State of Pennsylvania, and the Philadelphia County Medical Society.

Dr. Harry Huston Whitcomb of Norristown, Pa., died at Atlantic City on September 28 at the age of 61 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1880, and he was president of the Montgomery County Medical Society, a member of the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Dr. W. H. Barry of Hot Springs, Ark., a graduate of the Memphis Medical College in 1858, died at his home, after a lingering illness, on September 26, aged 80 years.

Dr. Nathan A. C. Mackie of Golinda, Texas, a graduate of the University of Tennessee, College of Medicine, Memphis, in 1881, died at his home, from apoplexy, on September 26, aged 64 years.

Dr. George Jacob Pierce of Worcester, Mass., died from heart disease, on October 2, aged 76 years.

Dr. John William McNamara of Denver, Col., a graduate of the Medical College of Ohio, Cincinnati, in 1901, and a member of the Colorado State Medical Society and the Denver City and County Medical Society, died at his home after a long illness, on September 19, aged 39 years.

Dr. Delbert Claude Adcock of Warrensburg, Mo., a graduate of the University Medical College of Kansas City in 1904, and a member of the Missouri State Medical Association and the Jackson County Medical Society, died suddenly on September 21, aged 36 years.

Dr. John A. McLeod of Milwaukee, Wis., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, died suddenly at his home, on September 21, aged 60 years.

Correspondence.

SURGEONS WANTED FOR THE EUROPEAN ARMIES.

To the Editor of the Medical Record:

Sir:—May I venture to ask that attention be called to the great scarcity of medical men in some of the armies of Europe—notably on the Eastern frontier. I am prepared to guarantee full officer's pay and traveling expenses to 150 competent surgeons for six months' service, or for the period of the war. An item to that effect would be highly appreciated and would probably lead to the prevention of much suffering.

Louis L. Seaman, M.D.

247 Fifth Avenue, New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ANNUAL REPORT—COUNTY OF LONDON—INFECTION IMPORTED—VERMIN—SCARLET FEVER—TYPHOID—KITCHEN ARRANGEMENTS—EPIDEMICS.

London, Sept. 21, 1916.

The annual report on the health of London has appeared as usual with the other statistics. There is a further decline in the population on that recorded for 1911, but it is only slight and is conjectured to be perhaps due to the difficulty experienced by poor persons with several children in obtaining suitable tenements within the county and being obliged to seek accommodation outside. This migration is also held to explain various other anomalies, *e. g.* those of sex distribution. At the age of 25 to 35 more females than males are attracted to London, unless ill health is present, when the reverse movement is observed. The mortality of young adults, especially females from phthisis, is understated in large towns, but, on the contrary, overstated in rural districts, because immigrants to towns return to their country homes when fatally ill, and the same may be said as to other chronic diseases. The expectation of life for London is greater in the last than in any previous returns, the increase being for all periods for women and for nearly all for men. The marriage rate for the year was higher than it has been since 1874, which is being attributed by many to the effects of the war. The birth rate continues to decline; it is now 24.3 per 1,000 as against 25 for the years 1909-13. In only one London borough (Chelsea) is there a rise, and that slight. We have again a very low death rate—only 14.4 per 1,000. The first quarter of the year had the highest incidence; the second, the lowest. Migration has an important effect on the birth rate. Domestic servants in London, who come from the country, frequently return to their homes on marriage. The infant mortality was 104 as against 107 for the previous quinquennium. The greatest number of deaths was due to wasting diseases, premature birth being a primary cause, followed by debility, marasmus, diarrhea, and afterward infectious diseases. The registrar-general's report for 1913 showed a low mortality from abdominal tubercle in London, but there is a heavier mortality from meningeal tubercle, though this is considered by some as only apparent through improved certification.

Great care has been taken to prevent infection being brought from abroad during the war and though some cases were scheduled at the port of London prompt measures were taken and so far seem successful. In the last report 41 per cent. of the children born were unaccounted for as concerning vaccination. The scarlet fever rate was higher, the females being more often affected, but the death rate was higher in the males.

In regard to this disease the prevalence of vermin has been studied. The waves of scarlet fever show crests every few years—say six to eight—and there is a correspondence of this with one showing the prevalence of fleas and also waves of dryness. A contrast of the curves of two sets of schools shows curves for London boroughs—one with the worst social conditions; the other with the best. In the worst the fever was highest in the youngest years and the decline fairly rapid; in the best the rise was delayed and the decline slower. The children in the poorer class of schools had less fever than those of the better class. It is conjectured that the poorer class had had the fever previously or had become immune to flea bites.

There was an outbreak of typhoid fever at the turn of the year 1913-14 and the infection was traced to one establishment and suspicion was directed to the kitchen arrangements—then to the food supply, but it could not be shown that this was certainly the source of infection. Out of 789 cases notified information was obtained about 400. The "trash" sold in London streets is almost certainly a frequent source of infection and in some large towns the water supply is blamed; so is fish, especially shellfish coming from a distance.

The great improvements in the sanitation of London during the last 30 or 40 years have done much to hinder the growth of the typhoid germ and deliver us from epidemic outbreaks, but the importation of cheap and "nasty" food must be constantly guarded against.

Progress of Medical Science.

2. Treatment of Diabetes. F. Fremont-Smith.
3. Insufficient Oxygen Supply as a Factor in Disease. Francis H. McCrudden.
4. Roentgentherapy in Hypertrophy of the Thymus Gland. Philip H. Cook.
5. Guillaume Dupuytren, 1777-1835. William Pearce Coues.

2. Treatment of Diabetes. — F. Fremont-Smith reviews the literature with reference to the starvation treatment of diabetes and calls attention to a new sign in persons developing coma, namely, the rapid decrease of intraocular tension, this lowered eye tension running with equal pace the advance or recession of coma. He says that since the diabetic fails to a greater or lesser extent to metabolize starch and sugar, and since his ability to convert these into fat, or to elaborate any form of food, to the extent of one with healthy tissues, is impaired, it is apparent that he must restrict both amount and quality of food below that taken in health by one of similar weight and height. The limitation of the carbohydrate will be determined from time to time by the glycemia and presence of sugar in the urine. Hyperglycemia and urinary sugar do not run *pari passu*, since permeability of the kidneys to sugar differs in different patients and at different times. The dietetic system recommended requires about 50 grams or 200 calories of carbohydrates daily; the average man takes six or eight times this amount. The carbohydrate intake must be begun at this low point and gradually increased, the rate being dependent upon hyperglycemia

and the appearance of glycosuria. The writer finds Kellog's graduated tables, reckoned on the standards of Chittenden, Lusk and Folin, a very practical guide for feeding carbohydrates, fats, and proteins, increasing or decreasing each element as the uranalysis indicates. For each pound of body weight one should give daily in calories, to begin with carbohydrate 0.5 calories, protein 1.5 calories, fat 0.2 calories, and gradually increase, if sugar-free, up to carbohydrate 4 calories, protein 1.5 calories, and fat 10 calories. On this basis a person weighing 130 pounds, reaching this intake at the end of two weeks, will be taking 2,015 calories in twenty-four hours. Fasting days are ordered weekly or less frequently, followed by two or three green vegetable days. Abundant water is necessary even up to 4 quarts daily and exercise should be graduated according to strength and results. The bowel movements must be kept free by bulky vegetable food, containing abundant cellulose, also by bran and paraffin oil, and the skin must be kept active by cold friction and hot baths, or, if under institutional treatment, by electrical and hydrotherapeutic means. This method of treatment once appreciated, becomes quickly simple, easily managed, and offers renewed courage and enthusiasm to both physician and patient.

3. **Insufficient Oxygen Supply as a Factor in Disease.**—Francis H. McCrudden urges that in the training of physicians more emphasis should be laid on the practical aspects of physiology. He says that the best evidence that the medical student does not receive adequate instruction in the practical aspects of this important subject are the primitive notions of physiology so frequently exhibited in the explanations of the mechanism of disease and the mode of action of different forms of treatment given in our clinical journals. As an example of this he cites the constant recrudescence of the myth of "insufficient oxygen supply," for over a century a favorite explanation of pathological symptoms. The belief in "insufficient oxygen supply" is based on an erroneous notion of the nature of metabolism, according to which the amount of oxidation is regulated by the respiration. The source of this error may be traced to Lavoisier, whose writings also contained a germ of the truth. Voit (1866) was the first to incline physiologists to the belief that respiration is not the cause of metabolism, but the result of the needs of metabolism. He pointed out that the carbon dioxide eliminated is independent of the ventilation of the lungs. In the cell alone lies the essential secret of the regulation of the oxygen used by the body; it is not determined by blood pressure, the velocity of the blood stream, the activity of the heart, or the activity of the respiration. No physiologist has contended that the products of incomplete oxidation will result from either poor respiration or poor circulation. It seems that sufficient time has elapsed for these facts to have filtered into clinical medicine and that more active emphasis will be placed on the practical aspects of physiology which will purge clinical medicine of ideas generally recognized by physiologists as incorrect.

4. **Roentgentherapy in Hypertrophy of the Thymus Gland.**—Philip H. Cook discusses the anatomy, development, and physiology of the thymus gland and reports several cases of enlarged thymus successfully treated by roentgen irradiation. He emphasizes Lang's conclusions: 1. Roentgen irradiation of the thymus produces artificial involution of the gland. 2. *X*-ray therapy is the method of choice in cases of enlarged thymus in children, whether the symptoms be mild or urgent. 3. Urgent cases should receive repeated massive doses. 4. Recurrences due to regeneration of the gland are to be watched for and controlled by further treatment. 5. Children whose physical or mental development is retarded should, if suspicion is directed toward the thymus, receive tentative *x*-ray treatment, even though a positive diagnosis cannot be established. 6. *X*-ray therapy as a precautionary measure, or preoperative treatment may enable children of the so-called lymphatic type to withstand intercurrent disease or anesthetics, which would otherwise prove fatal. 7. Preoperative exposure of older children and adults, where there is a suspicion of enlarged thymus, might lessen operative mortality. 8. Routine preoperative *x*-ray treatment in cases of hyperthyroidism should be resorted to with a view to lessening operative mortality. 9. *X*-ray exposure of the thymus gland has been proven harmless, whether in normal or abnormal individuals. A therapeutic test with the *x*-ray is, therefore, always permissible.

1. **The Therapeutics of Hay Fever.**—A. Parker Hitchens presents a historical review of the various theories as to the causation of hay fever and of the types of treatment that have been employed. He suggests the following plan of treatment: First, a thorough rhinoscopic examination in order that any condition requiring surgical treatment may receive attention. In the meantime a diagnosis is made with regard to the varieties of pollen to which the patient is susceptible. As an aid in identifying the pollens inhaled by the patient a special button should be worn by the patient or kept in his vicinity, consisting of a metal frame in which is held a microscope cover-glass coated with the glycerine mixture used by Blackley. The microscopic examination is made after about twenty-four hours' exposure. Prophylactic treatment may be begun two or three months before the hay-fever season. An initial dose of extract containing 0.0025 mg. nitrogen is sufficient to elicit some immunizing response without producing disagreeable effects. Subsequent injuctions are given at five to seven day intervals and may be increased to 0.01 and 0.02 mg. If the area of redness about the point of the first injection has been only slight the second dose is increased to twice the original amount. No further increase is advised. During the season the period of relief following an injection has been found to be variable. A few persons are relieved for only twenty-four hours; in such cases daily doses are necessary. In others the five or seven day interval between injections may be satisfactory. If the symptoms persist in spite of an apparently accurate diagnosis and specific treatment bacterial vaccines are well worth trying.

2. **Acute Intussusception in Infants.**—Benjamin T. Tilton believes that the mortality of operation within twenty-four hours after the onset of acute intussusception in infants should not be materially higher than that of appendicitis operated upon in the same period—that is, practically nil. Fatal results are due to two factors working separately or in conjunction. failure to make the diagnosis early, and faulty operative technic. As regards the differential diagnosis the only condition which comes into consideration is acute colitis. Here the onset is not so sudden or painful. Furthermore the passages are more copious and contain bile, while in intussuscep-

tion the movements are not large and contain only mucus and blood. The diagnosis should be followed by immediate operation, which should be performed with the minimum amount of handling of intestine and traumatism. The best incision, in the author's experience, is one that splits the rectus at the junction of its middle and inner third, and extends one-third above and two-thirds below the umbilicus. If possible the tumor mass should be grasped with two fingers and brought out through the incision, and all further manipulations performed outside the abdomen. Reduction of the intussusception is successful in between 80 and 90 per cent of the cases. Any other procedure besides reduction is so extremely unsatisfactory that every effort should be made to complete reduction. If reduction fails, resection with end to end anastomosis probably offers the best chance of recovery; but the mortality is excessively high, as the case is usually a neglected one. The formation of an artificial anus is attended with practically 100 per cent mortality. The efficacy of attempts to prevent recurrence by such means as anchoring or shortening the mesentery are doubtful and prolong the operation. In closing the abdomen, tension sutures of silkworm gut should be inserted through the skin and aponeurosis, in addition to the layer sutures. Special efforts should be directed to combat shock.

4. Occupational Thecitis.—Adolph Cohn states that thecitis is common as a result of occupations such as dressmaking, cutting, pressing, and working in sheet metal. When one encounters this condition he should always look for a focus of infection and eradicate it. On the whole, the extensors are more commonly affected than the flexors. Extensors are also more commonly affected in those using shears, while the flexors are more commonly affected in those using sadirons. The symptoms clear up in a short time under proper treatment, while untreated they become chronic and result in impaired motion and function. Occupational thecitis is differentiated from tuberculosis thecitis by a history of tuberculosis, fever, and longer duration, irrespective of occupation; from suppurative thecitis, by fever, swelling, and history of digital or palmar abscess; from osteitis, periostitis, or osteoperiostitis, by swelling, fever, history of injury, and *x*-ray; from arthritis, by limited or impaired motion of the joint, history, and *x*-ray. Locally the author prescribes the following:

℞ Tincturæ iodi.....ʒi;
Unguenti belladonnæ.....
Unguenti ichthyolis..... āā ʒss.
M. fiat unguentum.

In addition, baking is of great benefit. Internally, syrupus ferri iodidi, half a dram, and syrup of hydriodic acid dilute, half a dram, is prescribed.

6. Iritis and the General Practitioner.—William L. Rhodes calls attention to the frequent failure of the general practitioner to recognize iritis, with the result that the patients are not treated or mistreated and permanent loss of vision in one eye follows. The symptoms in iritis are typical, consisting in a change in the color of the iris. It has a muddied appearance, and the luster and striated appearance of the healthy iris are lost. There is frequently a fine meshwork of blood vessels forming a halo around the cornea and perceptibly diminishing the further from the cornea they are situated. Miosis is in evidence and the reaction of the pupil to light and to mydriatics is diminished or lost. Posterior synechia appears and can be demonstrated by the installation of a mydriatic. The subjective symptoms comprise pain and photophobia, together with a decrease in visual power. Transient myopia and astigmatism are noticeable in all cases of iritis. The treatment is governed by the cause. In the rheumatic type atropine and dionin, together with hot, moist applications, constitute the local treatment, while internally sodium salicylate is given. A focus of infection responsible for the condition may be found in the tonsils.

10. Verify Your References. — Frank Place emphasizes the importance of accuracy in references, and gives reasons why it is desirable that medical writers should always verify their references. He states that the experience of writers and bibliographers has shown that the efficient bibliographic reference is the one containing the complete and correct answer to the questions, "Who wrote it?", "What is it about?", "When and where was it published?" Answering these questions, the citation should stand as it does in the *Index Medicus* and in the *Index Catalogue of the Library of the Surgeon General's Office*. In referring to a book the details are these: (1) Author's name, with initials; (2) title of book; (3) edition, other than the first; (4) place, publisher and date (imprint); (5) volume, and page therein if a particular statement is to be quoted. Unless references are verified from the originals, marvelous results are sometimes attained. Verifying references means work, but if they are not worth the work they are not worth printing.

1. The Relation of Choked Disk to the Tension of the Eyeball.—Walter R. Parker presents this experimental study on dogs and monkeys to prove, if possible, the relation between choked disk and the tension of the eyeball in the case of artificially increased intracranial pressure. Three theories have been advanced to account for the causation of choked disk, namely: the inflammatory, the toxic or chemical, and the mechanical. These three factors alone or in combination have been urged as the possible cause of the swelling of the disk in cases of intracranial pressure. In conclusion he states that (1) choked disk can be produced in the dog and monkey by artificially increasing the intracranial pressure. The most satisfactory results are obtained by the use of sponge tents. (2) When the intracranial pressure is increased by artificial tumors placed in the occipito-parietal region, one element in determining which disk will be affected first is the tension of the eyeball. (3) When the intracranial pressure is increased by artificial tumors placed in the occipito-parietal region, the nerve in the eye of least tension is the first to show the choked disk. (4) When the intracranial pressure is increased by artificial tumors placed in the occipito-parietal region, there is no direct relation between the location of the tumors and the eye first affected.

2. Report of Five Cases of Tertian Malaria Treated with Diarsenol Intravenously. — Frank C. Neff. (See MEDICAL RECORD, June 24, 1916, page 1163.)

3. Bronchiectasis of the Upper Lobes.—Thomas McCrae and Elmer N. Funk report five cases with necropsies. (See MEDICAL RECORD, July 1, 1916, page 32.)

4. Posture in Obstetrics.—J. W. Marcoe. (See MEDICAL RECORD, July 8, 1916, page 84.)

5. Premature Ventricular Systoles: Their Clinical Significance.—J. E. Griewe. (See MEDICAL RECORD, July 1, 1916, page 33.)

6. Pelvic Infections in Women.—Thomas J. Watkins comments on some special pathology with application to treatment. (See MEDICAL RECORD, July 8, 1916, page 83.)

7. Intestinal Obstruction.—J. W. Draper. (See MEDICAL RECORD, July 8, 1916, page 82.)

9. Trichinosis.—J. B. McNerthney and William B. McNerthney report immediate result following the intravenous injection of neosalvarsan. The scientific paper of Van Cott and Lintz and their unfavorable results in the use of salvarsan and neosalvarsan made them slow to use neosalvarsan; however, in their reported case they were rewarded with a most favorable result, which seems to prove beyond a doubt that in certain stages of the disease, at least, neosalvarsan intravenously is a rational method of treatment in trichinosis.

10. Blood Cultures in Epilepsy.—William B. Wherry and Wade W. Oliver state that in cultures from the blood of six cases of epilepsy they had failed to isolate the organism described by C. A. L. Reed as the *Bacillus epilepticus*. Dr. Reed gave them one of the cultures isolated by Dr. Hyatt from a case, and, so far as they could tell, this organism belonged to the *B. subtilis* group. It formed terminal and subterminal spores which, when mature, were almost central. It grew rapidly at 37° C. or 24° C. with a smooth or wrinkled dirty white layer on any of the ordinary mediums. Blood serum was rapidly digested, as was also the case in clot in milk. Acid was produced from dextrose, levulose, galactose, saccharose, and mannite. They decided to test its pathogenicity after they had proved to their satisfaction that it really could be isolated from the blood of epileptics. Dr. Reed kindly offered to allow them to make cultures in his cases; this was done by them in conjunction with Dr. Hyatt. Not only could they not isolate such an organism, but they also failed to find any bacteria in smears stained by the Gimesa stain and by Abbott's spore stain and other methods. Dr. Hyatt had shown them smears containing the spores of *B. epilepticus*, but they had been unable to find similar bodies in the smears which they made. Notes on the cases from which cultures were made are presented.

11. Bacteriological Study of the Blood of Seventy Epileptics, with Special Reference to the Bacillus Epilepticus of Reed.—H. Caro and D. A. Thom present this study, from which they found that in this series of 70 cases, with a total of 160 blood cultures, 156 proved to be sterile. The remaining four showed contaminations. Four cases with either myoclonus or hemiplegia also gave sterile blood cultures. In a series of 17 necropsies on epiliptics, Dr. Canavan was unable to find any organism resembling *B. epilepticus*. It seemed evident that in the 70 cases studied the epileptic syndrome was not due to the *B. epilepticus* of Reed.

The Lancet.

5. Pneumococcus Meningitis with Recovery following Vaccine Therapy. A. Carnarvon Brown.
6. A Crossed Hip Reflex in Enteric Fever. E. B. Gunson.
7. The Ground Level Latrine. F. E. Fremantle.

2. Differential Leucocyte Counts in Enteric and Dysenteric Convalescents.—I. Walker Hall and D. C. Adam have made differential blood counts in a number of healthy men as a basis for comparison, and then examined the blood films from convalescent cases of amebic and bacillary dysentery, typhoid, and paratyphoid fevers. They have not observed the distinct eosiniphilia which they had expected to find in these cases, the eosinophile percentages not having exceeded those met with in routine examinations of other forms of convalescence. This feature does not seem to offer much aid in the differentiation of an inoculation and an infective agglutinin when only one agglutinin is present in the blood. With regard to other types of cells, the evidence accumulated suggests that extended observations, with the addition of other important hematological procedures, may show that some information will be gained by the examination of blood films in cases of difficulty and especially in continuous fever in men who have been inoculated with mixed vaccines against typhoid, paratyphoid A and B, and cholera. It seems probable that when the agglutinin present is due to inoculations, the blood films will yield approximately normal films, while in the case of an infective agglutinin the typical leucocytosis or polynuclear leucopenia associated with the causal organism will be found. The counts obtained from recently inoculated healthy men would lead to the supposition that the cells which react to dead typhoid and paratyphoid bacilli may be proved to be of a different order from those which act upon living infective typhoidal organisms. These writers are not yet satisfied that the figures they have obtained from their paratyphoid examinations are really representative. There has been a difference between the counts yielded by the convalescents from the various war areas which are more than should arise from errors of technic or from personal factors. In the cases from the French area there is a persistence of mononuclear increase and polynuclear decrease in the paratyphoid A which is different from those in the Mediterranean area. The purely typhoid and paratyphoid cases show counts which differ from those yielded by the typhoid plus protozoa and the paratyphoid plus protozoa. The paratyphoid cases from the Mediterranean are approximate to the mixed type of counts both in their polymuclears and mononuclears as well as in the eosinophile cells. There is evidence pointing to the possibility that the cases in which the leucocyte counts differ materially from those of French origin may be ascribed to a mixed infection and put in a class by themselves. It is also possible that the lack of eosinophilia in the post-paratyphoidal cases may arise from the coexistence of amebic infection. It has been observed that leucocyte counts made a few weeks after the injection of a mixed typhoid-paratyphoid vaccine show a greater number of eosinophiles than do those obtained after a pure typhoid inoculation. If the results of these examinations are confirmed it would establish the contention of the writers that when clinical diagnosis is not upheld by serological findings the matter may be cleared up by timely examination of the total and differential leucocyte contents.

3. Notes on the Vaccination of Guinea-pigs with B. Perfringens.—Muriel Robertson gives an account of experiments carried out with *B. perfringens*, from which the general conclusion may be drawn that previous vaccination with killed or attenuated cultures of *B. per-*

fringens does not cause any appreciable raising of the resistance of guinea pigs against a subsequent lethal dose of living bacilli. Recovery from a previous infection with the organism does not prevent a reptition of the illness upon reinoculation with living bacilli, nor does it apparently in any way alter the symptoms or influence the course of the disease.

4. **Infective Jaundice: A Preliminary Report.**—N. B. Gwyn and J. J. Ower have been making a study of this condition since November, 1915, from which it appears that typhoid and paratyphoid bacilli can be excluded as causal agents in these cases. Japanese authors have described a spirochete in cases of epidemic jaundice, and the writers have made a search for this kind of an organism. They describe the method used, and state that aerobic cultures were negative, but on the fifth day examination of the material from the deep agar anærobic culture on the dark stage showed a few spirochete-like bodies. Similar bodies were found in the first examination of another specimen. These presented much the appearance of the *spirochæta pallida*, except that they were usually shorter, coarser, and not so regular or finely spiral. They were definitely motile, but had not the rapid spiral movement of *S. pallida*. In a Giemsa preparation they were not demonstrable; with the Fontana a small number were found to take the silver impregnation readily. The results of animal inoculation have thus far been negative, but the essayists think this may be due to the fact that they have received all their cases late in the disease.

6. **A Crossed Hip Reflex in Enteric Fever.**—E. B. Gunson writes that the crossed hip reflex has been noted in cerebral tumor, various cerebrospinal conditions, and in diphtheria. When the quadriceps femoris muscle is firmly grasped just above the knee between the thumb and fingers, the patient experiences considerable pain referred to the site of stimulation and there occur flexion at the hip joint and extension of the great toe of the opposite limb. The reflex may be incomplete and consist of flexion at the hip only or of flexion at the hip and contraction of the tensor fasciæ femoris muscle without actual contraction of the great toe; crossed extension of the great toe without flexion at he hip occurs in some cases. Pain on stimulation is a marked feature, and usually persists for several days after the reflex movements can no longer be elicited. This reflex has been studied by the author in thirty-seven cases admitted to the General Hospital, Alexandria, from Gallipoli. The reflex appeared as early as the second day of the disease, and in one case persisted into the eighth week; the time, onset, and duration were vary variable. The reflex bore no absolute relation to the severity of the disease, but tended to be more complete and persisted for a longer time in severe types. The presence of the reflex in enteric fever is held to signify a temporary perturbation of the spinal cord, the result of a toxic or inflammatory process, on which some of the other reflex changes observed in enteric fever may also depend, and to which the extreme weakness of the back and limb muscles may in part be attributed. The reflex was found to be of some diagnostic value, as it was never present in doubtful cases.

1. Gas Gangrene as Seen at the Casualty Clearing Stations. Cuthbert Wallace.
2. The Direct Transfusion of Blood: Its Value in Hemorrhage and Shock and in the Treatment of the Wounded in War. A. Primrose and E. S. Ryerson.
3. Trench Fever: The Field Vole a Possible Origin. W. J. Rutherford.
4. A Case of Ulcerating Granuloma Successfully Treated by Intravenous Injections of Antimony. George C. Low and H. B. Newham.
5. Lamblia Infections in Men Who Have Never Been Out of England. A. Malins Smith and J. R. Matthews.
6. A Case of Intrauterine Scarlet Fever. R. M. Liddell and C. E. Tanyge.

1. **Gas Gangrene as Seen at the Casualty Clearing Stations.**—Cuthbert Wallace says that gas gangrene is still a very striking feature in the surgery of the present war. Two very interesting papers have recently appeared by d'Este Emery and Kenneth Taylor, and if the two theories of the disease as given by these men are compared it will be found that they differ mainly in the part played by the gas. Taylor thinks that it plays an important part; d'Este Emery denies this, and believes that the bacteria toxins are the important factor. Taylor believes that the disease is mainly one of the muscles; d'Este Emery thinks that this is a mistake, and that it is only the fact of the bacteria being able to produce gas by the aid of the muscle sugar that leads to this assumption. These two views reflect somewhat different conceptions of the disease, but it seems probable that both observers have some right on their sides. The author's own impressions of the disease as seen at the front and gathered elsewhere may be briefly stated as follows: (1) It is rare to meet gas gangrene without a muscle injury. (2) It is chiefly a disease of the muscles, and is rarely dangerous unless muscle is involved. (3) The lesion in its early stages may be described as a longitudinal one. (4) It is rare to find all the muscles of a segment of a limb involved, save in a segment distal to one in which the main blood supply has been cut off. (5) The muscles affected are in the first instance the wounded ones. (6) Muscles contained in rigid compartments, such as the anterior tibial group, are especially prone to die if wounded. (7) There is but little tendency for the infection to pass from one muscle to another. (8) The infection is further advanced in the muscles than in the intermuscular areolar planes. (9) The muscles become resonant from the presence of gas long before they become prepitant to the finger. (10) The presence of gaseous crepitation does not necessarily mean microbic infection. (11) Crepitation is usually a comparatively late phenomenon, and is due to the escape of gas into the areolar and subcutaneous tissue. (12) In an infected limb a vascular lesion will be followed by the death of the muscle or muscle group, which death would not have followed in an uninfected limb. (13) In an infected limb there are several conditions of the muscles. (14) The microscopical appearances of muscle dead from cutting off its blood supply are different from those of a muscle dead from infection. The striation is present in the former and absent in the latter. (15) The bacteria are between the muscle fibers and not in them. (16) Microscopical examination suggests that the gas may find its way between the muscle fibers in front of the bacterial invasion. (17) In dead infected muscles the fibers are separated from one another. In the treatment of gas gangrene the circulation should be helped in every way. The bad effects of tight bandages must be insisted upon. In cases in which hemorrhage into a limb is continuing there is no doubt as to the advisability of finding the bleeding point. If the artery is a main one an attempt should be made to suture instead of ligate the vessel. Suture is worth while trying in a vessel locally thrombosed from the effect of trauma. In dealing with gas gangrene in a wounded segment of a limb and deciding on the advisability of amputation, it should be borne in mind that it is usually only the wounded muscles that become gaseous and that incision or ablation of such muscles is often sufficient to arrest the disease.

4. **A Case of Ulcerating Granuloma Successfully Treated by Intravenous Injections of Antimony.**—George C. Low and H. B. Newman describe this lisease, which

they state is a true venereal disease but has nothing to do with syphilis or the usual venereal diseases. It is very common in British Guiana, Brazil, and other parts of South America, and resembles in some ways the type of change seen in lupus or rodent ulcer. It is believed to be of protozoal origin. The case which the authors report was cured by the intravenous injection of antimony. The first injection consisted in 1 grain of antimony dissolved in 2 ounces of normal saline injected directly into the vein, the same vein being used time after time for the different injections. In all, fifty-three injections were given at intervals of three or four days. The dose was raised from 1 to 2½ grains after the first three weeks. It is suggested that a judicious combination of antimony and the *x*-ray would be worthy of trial and might shorten the length of the treatment.

5. **Lamblia Infections in Men Who Have Never Been Out of England.**—A. Malins Smith and J. R. Matthews report three cases of Lamblia infection, two of which certainly and the third almost certainly were contracted in England. These cases are recorded in view of the prevalent idea that infections of *Lamblia intestinalis* are associated with residence abroad. They were discovered in the routine examination of stools conducted at the Liverpool School of Tropical Medicine. In commenting on these cases the authors observe that it is almost impossible now and will shortly become quite impossible to offer any evidence as to whether *Lamblia* is indigenous in England. The presence of the very numerous cases of returned soldiers carrying *Lamblia* will make it impossible to state whether any future case is of native origin.

6. **A Case of Intrauterine Scarlet Fever.**—R. M. Liddell and C. E. Tangye report the following case as being unusual. Four of five children in a family, during a recent outbreak of scarlet fever in a small village, were removed to an isolation hospital on May 26. On June 6 the mother was delivered of a child which was found to be desquammating freely over the whole of the trunk and limbs, and the urine showed distinct traces of albumin. These features were so typical that it was decided to report the case as one of scarlet fever. The mother is positive that she had a severe attack of scarlet fever when 10 years of age. It would seem that the fetus was infected some time prior to May 26, and that the mother escaped infection through the protection of her previous attack. Presuming the fetus to have been infected from the children in the family, the period elapsing between the infection and the peeling stage must have been only a fortnight. The writers quote authorities who raise the question of the possibility of such an occurrence, but hold that while the rarity of the condition may be somewhat against the diagnosis, the clinical facts were so striking as to make them worthy of note.

Decalcification Consecutive to the Traumatisms of War.—"J. J." states that while the osteotrophy of accidents to workingmen has been well studied by radiography, the forms due to projectile traumatisms have hardly fixed the attention. However, Surgeon-General Delorme has just caused to be published a memoire on this subject. The characteristics of this calcification are connected solely with the radiograph examination. This characteristic is the great translucency of the bones. The articular lines are well preserved, which evidence is valuable for the exclusion of ostertis. The short bones are much more prone to suffer than the long ones. These osteotrophies are of great frequency, but at present but little is known of the date of supervention, duration, pathogeny, and respective influence of defective nutrition and innervation. Between ostertis and ordinary osteoporosis or decalcification there are these differences: The latter is uniform, while in ostertis the changes are irregular. The suppression of the articular line in ostertis has already been mentioned. In osteoporosis the trabecular architecture of the bone is preserved, while in ostertis the reverse is true. For the treatment of decalcification as a result of firearms, there are as yet no strict indications. Electricity used with the aim of stimulating nervous influence is without benefit. Antisyphilitic remedies given to syphilitic subjects are also without effect. Recalcification is the theoretic remedy, and lime salts are being given inwardly. Good results are not yet forthcoming.

On the Control of Medical Thermometers.—According to "J," who is giving a synopsis of a meeting of the Academy of Medicine, the accuracy of the clinical thermometer leaves much to be desired. The French formerly obtained all their supplies from Germany, because in the latter country they can be made at a price which defies all competition (they sold at from 0.4 to 0.66 francs a piece). At present the old German supply has been superseded by goods from Switzerland, England, and the United States, sold at a much higher figure. A committee of the Academy, having been appointed to investigate this subject, reports that the new thermometers often lack a guarantee of exactitude, which makes possible grave errors of diagnosis. There should be some authorization for official control, so that the instruments cannot be used unless tested carefully beforehand. This could be effected completely by encouraging a national industry, made possible only by a special tax which should be lowered to such a degree that the present selling price should be but slightly advanced. The control should be carried out through activities of the Conservatoire des Arts et Metiers.

Wide Primary Subperiosteal "Esquillectomie" in the Treatment of Fractures by Artillery Projectiles.—The word esquillectomie, which has come into extensive use during the present war, has no exact equivalent in English. In the older treatment of splintered fractures every effort was made to save fragments of bone and allow them to heal in, even often to nail or wire them in. While the word "esquille" is equivalent in English to splinter, the latter suggests a small, pointed fragment, while in "esquille" in the present sense there is no limit as to size. Since in military injuries detached fragments of bone may soon become necrotic, the operation of removing them might be regarded as akin to sequestrotomy. Leriche writes at length on the evil influence exerted by small splinters of bone revealed only by radiography. These are very irritating and may arouse a latent infection. To remove them is therefore a step in prophylaxis. The author reports fourteen fractures of the diaphyses of the bones of the forearm and leg. The radiograph revealed the presence of detached fragments which would surely have become necrotic. In a number of cases these pieces of bone were removed as foreign bodies, covered with dirt or shreds of clothing. In the main, however, under local anesthesia (ethyl chloride) suppuration had begun and the author, with much pains, removed all detached fragments. The suppuration could have been prevented had the fragments been removed at the first dressing. The removal of large fragments, as in the tibia and

femur, was effected by the subperiosteal route. Instead of becoming infected the broken bones under radiographic control could be seen to unite tolerably well under callus formation. Conservative surgeons fear various kinds of mischief, and especially pseudarthrosis, but the author's results show that this fear is unfounded. The same is true of the dangers of ostertis. The residual periosteum does much to enhance union. Leriche would establish a rule to use this operation in all fractures of artillery origin, in the interest of normal, aseptic healing.

Dysentery and Dysenteriform Diarrhea. — Giroux states that of 150 cases of diarrhea treated by him, 40 were of the familiar type, 117 were examples of so-called dysenteriform diarrhea, while 3 were choleriform. But 5 cases ended fatally. In the dysenteriform column, convalescence was always announced by a urinary crisis—a profuse diuresis after a period of scanty prine. An associated phenomenon was bradycardia. In 3 patients the dysenteriform type was associated with paratyphoid. Both kinds of bacilli were present (dysentery, paratyphoid B.) In the other cases the *B. dysenteriæ* could not be detected. The first case ended fatally. In regard to treatment, serum is given only when the dysentery bacillus is present or the clinical syndrome perfect. But this serum often seems defective in the most typical cases of dysentery. Under such circumstances we can only give emetine, which, generally speaking, gives prompt and good results. In other words, the dysentery is essentially anieboid, with occasional coincidence of the bacillus of bacillary dysentery.

Journal de Médecine de Bordeaux.

September, 1916.

Iodine and Gas Asphyxiation.—Boudreau is a partisan of iodine in the treatment of many infections—fevers, infectious enterities, etc. He has been testing it with truly remarkable results on victims of gas asphyxiation He had long regarded the drug as the heroic remedy for pulmonary affections, including tuberculosis. Lesions from gases comprise bronchitis, congestion of the lungs and bronchopneumonia, in association with failure of the general health. Iodine exerts a salutary action on all these lesions, and the sequelæ which they furnish, and tends to prevent the evolution of tuberculosis. The author believes that iodine can to a certain extent conserve some of the living tissues which would otherwise soon be sacrificed to disease. The drug also possesses antitoxic powers which combat the toxic blood states induced by these gases. Thus it can prevent the secondary eye changes. The author would treat a case of gas poisoning just as he would a case of pulmonary tuberculosis; and such treatment should be both progressive and intensive. The tincture should be given in any fluid vehicle—milk, for example. It may even be placed in any drink which the patient uses—even beer. The initial dose is very small—a drop or two in each glass or cup of fluid taken. The dose on the second day should not exceed 2 drops, the next day 3, and so on. The number of doses should reach 5 to 8 daily. There is no maximum. Some of the author's consumptives have consumed as much as 600 drops of the tincture in 24 hours, and over 60 drops may be taken as a dose. This medication may be maintained for months. Hernoptysis is no contraindication. The main aim of the author appears to be to secure a general trial of iodine therapy in victims of gas poisoning, based on his personal experience. Results of others are not mentioned.

Cancer of the Vertebræ.—"J. R." gives an abstract of a valuable study on this subject by Montanaro of Argentina. Three cases are reported in great detail with superb illustrations. In all cases the growths were intrinsic. The first symptons were very painful radicular neuralgia. These were aggravated by heat or cold, were boring or lancinating, and were worse at night; often they were so severe as to prevent walking. Radiography revealed nothing precise. Study of lumbal punctates had indicated hyperalbuminosis and hyperleucocytosis. Other symptoms were those common to cord compression (paraplegia, atrophy, abolition of reflexes, troubles of urination).

Thymic Disturbance in the Adult.—George H. Hoxie relates the history of a number of cases in which the condition had been diagnosed as neurasthenia or myasthenia. This group of cases has in common enlargement of the thymus, shortness of breath and extreme weakness, but shows no gross pathological changes. Variability of the pulse and blood pressure, subnormal temperature, and atony of the gastrointestinal tract, in patients showing no evidence of organic disease, are additional symptoms pointing to the endocrine disfunction. The dulness is usually noticed when percussing the manubrium sterni. If the dull area extends out a half inch or more on either side of the manubrium, and if the manubrium is duller than the corpus, one should proceed with differential tests. Gentle percussion rather than the stronger type is necessary to bring out a body so closely adherent to the posterior surface of the bone. Under such ordinary percussion the dull area is that of a triangle with its base just below the interclavicular notch and its apex between the junctions with the sternum of the second and third ribs. The aortic dulness does not reach as high as the center of this area and does not lie as symmetrically under the sternum. An intrathoracic thyroid might give a similar dull area, but this could usually be found to extend above the interclavicular notch and move with the act of swallowing. Aneurysms of a size sufficient to cause substernal dulness would give also a thrill of pulsation. The fluoroscope should be used to verify all cases in which the percussion would indicate thymic enlargement. In making this examination, when one sees a mass in the sternum, one should keep in mind the questions: "Does it have a movement of its own? Does it have a definite form through which the bones are seen more indistinctly?" The treatment of the condition demands rest and forced feeding, with attention to the emunctories and the environment. The medical treatment calls first for the use of arsenic in heavy doses. It would seem as if the thyroid gland furnished the best material to permit the thymus to sink back into quiet. This the author has worked out by trying the various glandular extracts. He says one would suppose that the adrenal extracts were of particular value, but thus far this has not been clinically verified.—*New York Medical Journal.*

Acute Abdomen Following Trauma.—G. B. Kunkel summarizes his article as follows: Do not hold lightly any trauma of the abdomen, but watch carefully and treat expectantly. Do not wait for a patient to bleed to death. If a hollow organ is suspected to be perforated, operate at once. Operation delayed over eighteen hours in a case of perforation gives a very grave prognosis. Purgatives have no place in an acute abdomen. Let the severe pain, tenderness and rigidity be the red flags to place you on guard and guide you to a happy issue in the recovery of the case. Do not forget that a delay of twelve hours in perforation can place the balance against your patient. Do not mask symptoms by morphine. Diagnose speedily.—*International Journal of Surgery.*

Insurance Medicine.

Association of Life Insurance Medical Directors.—The twenty-seventh annual meeting of this Association will be held in New York on Wednesday and Thursday, October 25 and 26, 1916. The following papers will be presented: Address by the president, Dr. Franklin C. Wells, on "The Functions and Scope of the Medical Department"; "Conservation Work and Life Insurance," by Dr. Thomas H. Willard; "Life Expectancy Following Operation on the Gall-Bladder," by Dr. Charles H. Mayo; "The Need in Medical Selection of Standards by which to Measure Borderline Risks," by Arthur Hunter, Esq., and Dr. Oscar H. Rogers; "The Best Way to Obtain Better and More Careful Medical Selection from the Examiner in the Field," by Dr. William R. Ward; "The Best Way to Get an Examiner to Use the Sphygmomanometer," by Dr. P. E. Tiemann; "Urine Examinations," by Dr. David N. Blakely; "The Importance of Glycosuria in Life Insurance," by Dr. J. Allen Patton; "Selection of Women," by Dr. T. H. Rockwell; "The Heart Beat and Its Irregularities," by Dr. Laurence D. Chapin.

Relative Frequency with Which Obesity Is Found Associated with Different Diseases.—In a paper read before the Assurance Medical Society in London Dr. F. Parkes Webber discussed this question. Among the most recent statistical data bearing on the point are the following:

During the years 1913 and 1914 an Italian assurance company, Istituto Nazionale delle Assicurazioni, rejected 308 obese candidates. In 36.38 per cent. the obesity was apparently without complications; in 21.75 per cent. it was associated with glycosuria; in 10.38 per cent. it was associated with nephritis; in 7.18 per cent. it was associated with albuminuria; in 5.84 per cent. it was associated with heart trouble; in 5.19 per cent it was associated with arteriosclerosis; in the remaining cases there were various complications, such as syphilis, alcoholism, bronchial catarrh, etc. (I. Romanelli, *Il Policlinico,* August 8, 1915.) The following statistical table was obtained from the Life Assurance Data of the "Viktoria" office in Berlin: (Bruno Moses, "Die Fettleibigkeit in ihrer Beziehung sur Lebensdauer und Todesursache." Berlin, 1906, p. 23.)

Cause of Death.	In All Assured Persons, Per Cent.		In the Corpulent, Per Cent.
	During the Three Years 1900-1902.	During the Three Years 1903-1905.	
Acute diseases of the respiratory organs	11	12	11 1
Chronic diseases of the respiratory organs (pulmonary tuberculosis)	17	14	5.4
Diseases of the heart	13	14	18.9
Diseases of the kidneys	...	...	...
Apoplexy	9	9	13.8
Malignant tumors	Not given	8.3	9 8
Diseases of the liver	Not given	2.1	4 4
Diseases of the blood	0.8	1	1.5
Alcoholism	1.5	1	0 2
Surgical diseases (erysipelas)	5	1	3 9

The following table shows the percentage of deaths among 26,222 dying from all causes, classed as overweights and underweights (i. e. 20 per cent. variation from normal). It is from the experience of the Connecticut Mutual Life Insurance Company, 1846 to 1895, inclusive, quoted from Shepherd in Green's "Medical Examiner."

Cause of Death.	Underweight (Per Cent. of Deaths).	Overweight (Per Cent. of Deaths.)
Tuberculosis	22 0	1.9
Rheumatism and gout	1.1	2.2
Diabetes	0 0	3.5
Nervous diseases	14 0	23.0
Heart disease	6.0	15.5
All circulatory diseases	7.8	17.9
Pneumonia	12.0	6.5
All respiratory diseases	16 4	9.0
Digestive diseases	7 5	8.5
Kidney diseases	5 2	9.7

G. M. Low, in an article on "Extra Rating as a Statistical Problem," quoted by Greene, gives the following table showing the number of actual and expected deaths among obese persons:

Cause of Death.	Actual Deaths (Stout Persons).	Expected Deaths (Healthy Males).	Percentage of Actual to Expected.
Diseases of the urinary organs	6	3	200
Diseases of the digestive organs	14	8	175
Diseases of the circulatory organs	10	7	143
Diseases of the respiratory organs	12	9	133
Diseases of the brain and nervous system	16	14	114
Diseases of uncertain seat (tumor)	1	3	33
Zymotic diseases	8	10	80
Sudden and violent deaths	3	4	75
Tuberculous diseases	0	8	0
Causes not classified	4	2	200

The following table of causes of death in regard to fatness or leanness of the assured is from Arthur Hesse, "7066 Todesfälle der Basler Lebens-Versicherungs-Gesellschaft," Leipzig, 1899:

General Nutrition When Accepted for Life Assurance

Cause of Death.	Lean.		Medium.		Corpulent.	
	Total.	Per Cent.	Total.	Per Cent.	Total.	Per Cent.
Infectious diseases	48	15.64	179	58.31	80	26 05
Cancer	106	16 56	391	61.10	1.43	22.34
Tuberculosis	389	23.61	1,077	65.35	182	11.04

E. H. Kisch, writing on "Fettsucht," in "Eulenburg's Real-Encyclopädie der gesammten Heilkunde," Vienna, 1895, says that in 19 necropsies on corpulent persons who had died suddenly the causes of death were found to be acute edema of the lungs in 12 cases, cerebral hemorrhage in 6 cases, and rupture of the heart in 1 case. In autopsies on corpulent persons whose death was not sudden, Kisch found that in nearly two-thirds of the cases of fatty heart, cardiac hypertrophy and dilatation were likewise present; in many cases, sometimes in relatively young individuals, arteriosclerosis was associated with fatty heart. One-third of the subjects died from cerebral hemorrhage. In nearly all the cases there was some pathological change in the kidneys, varying from passive congestion to granular atrophy. In half the cases there was fatty liver.

Book Reviews.

Muscle Training in the Treatment of Infantile Paralysis. By Wilhelmine G. Wright, Boston Normal School of Gymnastics, 1905; Chirurg.-orthopäd. Klinik of Prof. Dr. A. Hoffa, Berlin, 1908; Assistant to Robert W. Lovett, M.D., Boston. Second edition. Price, 25 cents. Boston: Ernest Gregory. 1916.

This is a very practical and timely treatise on the reconstructive treatment of the paralysis following poliomyelitis. Dr. Lovett is one of the recognized authorities on the after treatment of this malady, and Miss Wright's methods have been developed in accordance with his teachings and are the result of her experience during many years of association with him in orthopedic work. The little book cannot fail to be helpful to every physician who is called upon to advise in the case of a victim of this crippling disease.

Surgical Nursing and Technique. A Book for Nurses, Dressers, House Surgeons, etc. By Charles P. Childe, B.A., F.R.C.S. Eng. Lieut-Col. Royal Army Medical Corps (Territorial), Senior Surgeon, Royal Portsmouth Hospital, Medical Officers in Charge of the Surgical Division, 5th Southern General Hospital, Portsmouth. Price, $2.00 net. New York: William Wood and Company, 1916.

In Surgical Nursing Mr. Childe has produced an extremely useful manual. The first edition was issued under the title of "Operative Nursing and Technique" and proved very popular. It deals wholly with operative nursing and is mainly intended for the large class of Sisters and nurses who find themselves saddled with the great and interesting responsibilities of modern operative nursing, either in hospitals or private homes or houses. The second edition has been brought thoroughly up to date and contains a chapter on nursing in military hospitals. The book may be strongly recommended to nurses as a practical and clear exposition of their surgical duties.

On Modern Methods of Treating Fractures. By Ernest W. Hey Groves, M.S., M.D., B.Sc. (Lond.), F.R.C.S. (Eng.); Surgeon to the Bristol General Hospital; Consulting Surgeon to the Cossham Hospital; Late Hunterian Professor of the Royal College of Surgeons of England; Major R.A.M.C. in charge of the Surgical Division of the 21st General Hospital, British Expeditionary Force. Octavo of 286 pages with 136 illustrations. Price, $2.75 net. New York: William Wood and Company, 1916.

This is a book of much scientific interest. The handling of the subject is for the most part along general lines and about one-third of the text is concerned with the description of the author's experimental work on animals and the deductions, comments and conclusions based thereon. The author has aimed "to show that the various methods of treatment should all be brought into our service as occasion requires, instead of being regarded as independent, rival, or mutually destructive systems; and, secondly, to emphasize the necessity for mechanical accuracy and efficiency in dealing with what after all is largely a mechanical problem."

In the introductory chapter entitled: "The myths of yesterday and the problems of today," Groves suggests that in comparison with the development in other fields of surgery the treatment of fractures has lagged behind; and that the common practice of today is probably more like that of a thousand years ago in this department than in any other. He pays a tribute to Bardenheuer, Lucas-Championnière, and Lane, who have been pioneers in getting us away from what he calls the methods of medieval surgery in the case of broken bones. Among the myths is the idea that the average fracture is "set" in the sense that the fragments are placed in accurate apposition and alignment when we speak of "setting" the bone. The *x*-ray has shown that old ideas on this point needed to be revised. Other so-called "principles" in the classical treatment of fractures by immobilization come in for ridicule or caustic criticism.

After discussing the relation of the *x*-ray to the treatment of fractures, the relation between form and function, and other matters, he proceeds to the discussion of fracture treatment under present day conditions. The new methods are grouped under three main divisions and several sub-divisions. The main divisions are: I. Methods of Massage and Mobilization; II. Extension Methods; III. Operation Methods. These latter involve the exposure of the seat of fracture, the direct reduction of the deformity, and fixation by wire, plates, screws, pegs, or grafts. Each method is discussed in detail and one gets a good general idea of their uses and limitations, the one remarkable exception being that almost no space is devoted to the consideration of the value and technique of applying the bone graft, a method that, in this country at least, has been used extensively and bids fair to supersede many of the operative methods to whose consideration Groves devotes a considerable portion of his book. There are many suggestions of great value to the skilled surgeon and many of the devices which Groves has originated or adapted are worthy of general adoption in properly selected cases and should be beter known.

While, as we have intimated, this is a book that will appeal especially to the operating surgeon who is interested in the scientific aspects of the subject, there is much that will also appeal to the general practitioner; and none can fail to have a better appreciation of the problems of fracture treatment after reading it.

Gynecology. By William P. Graves, A.B., M.D., F.A.C.S., Professor of Gynecology at Harvard Medical School; Surgeon-in-chief to the Free Hospital for Women, Brookline; Consulting Physician to the Boston Lyin-in Hospital. Large octavo of 770 pages, with 303 half-tone and pen drawings by the author and 122 microscopic drawings by Margaret Concree and Ruth Huestis, with 66 of the illustrations in colors. Price, cloth, $7.00 net. Philadelphia and London: W. B. Saunders Company, 1916.

In writing the work the author had in view its use both as a text-book and as a work of reference. This is not always a happy combination because the needs of the undergraduate and the practitioner are generally so dissimilar; but because of the division of the work into three parts, each more or less independent of the others, the reader of one class who is looking up a subject is not obliged to read what is intended for the other. This will be better understood when we state that Part I, of 135 pages, deals with the physiology of the pelvic organs and the relationship of gynecology to the general organism; Part II, of 375 pages, "is designated primarily for the undergraduate student who is taking his initial course in gynecology," and includes a description of those diseases that are essentially gynecological; while Part III, of 225 pages, is devoted exclusively to the technique of gynecological surgery.

In each section the subject matter is taken up in logical fashion and the various subdivisions in the discussion of any particular subject are made at once apparent to the reader by the judicious employment of various sizes of heavy-faced type. As far as possible the author has omitted extended textual descriptions when the points in question could be as well or better shown by illustrations with appropriate legends. This applies especially to the microscopic appearances of normal and pathological tissues and to the section devoted to operative technique.

The Dream Problem, by Dr. A. E. Maeder, of Zurich. Authorized translation by Drs. Frank Mead Hallock and Smith Ely Jelliffe, of New York. Price, 80 cents net. New York: The Nervous and Mental Disease Publishing Co., 1916.

This little book presents another view-point of the dream problem. Freud looks upon the dream as the representation of an unfulfilled wish and lays stress upon the activities of the repressing mechanism which he calls the endo-psychic censor. Stekel sees bisexuality in every dream and also thinks that the thought of death appears somewhere in it. Adler sees in the dream an abstracting, simplifying endeavor to find a protective way for the ego-consciousness out of a situation which threatens a defeat. Dr. Maeder, however, sees in the dream a possible solution of the problem confronting the individual and therefore ascribes a constructive rôle to it. He attaches a greater importance to the manifest dream content than Freud does. The dream, he says, is perhaps the primitive work of art. It is prospective as well as retrospective and points the road for the patient to follow. It has a preparatory arranging function belonging to the work of adjustment. This preparing function is Maeder's contribution to the study of dreams and has been severely criticized, especially by the Vienna school. The translation reads very smoothly which is always a triumph in an English rendition of German psychoanalytic material. Like all the works in this monograph series, this book is published with paper covers which makes it necessary to rebind if it is to see much use.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 5, 1916.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

The Management of Poliomyelitis with a View to Minimizing the Ultimate Disability.—Dr. ROBERT W. LOVETT of Boston presented this paper. (See page 705.)

Dr. SIMON FLEXNER said that the subject of Dr. Lovett's most excellent paper was one that should properly be discussed not by a pathologist, but by an orthopedic surgeon, from the point of view presented, though it was a pleasure to him to be asked to open the discussion because he had followed with interest the work of Dr. Lovett in Boston and in Vermont in which he had carried into effect principles and methods of after-care of the paralyzed which appeared to be an improvement over older methods of treatment. Dr. Lovett had based his views on the pathology of the disease which was the logical way to approach the subject; and he had done the speaker the honor to employ in his description conceptions and explanations which the latter's studies had been responsible for. The basis of the modern conception of poliomyelitis was that it was an infectious disease in which the paralysis was merely an incident and an accident and by no means a necessary part. The percentage of cases in which paralysis occurred was not yet established, but it was probably much lower than had been previously believed. Had the pathology of the disease been worked out originally in artificially infected animals, this confusion would never have occurred. Nevertheless, Wickman had discovered clinical types of the affection in which paralysis never occurred. But experiments on animals and the employment of lumbar puncture both showed that, whether or not paralysis occurred, changes took place in the cerebrospinal membranes and fluid which indicated implication of the meninges in the pathological process. In many cases no invasion of the substance of the brain and spinal cord occurred. When invasion did take place, it was through the lymphatic structures about the blood-vessels which became infiltrated with cells—usually of lymphoid type. In a proportion of cases the process went on further than this; but it was common that when so much involvement had arisen, actual infiltrations occurred in the nervous tissues—the grey matter of the cord especially but also the white matter in far less degree and not only the anterior grey matter of the cord, but the posterior also and the intervertebral ganglia which were among the earliest structures to show lesions. The infiltrative process damaged the nervous tissues and thus interfered with function in two main ways: the cellular invasion of the sheath of the blood-vessels obstructed the lumen and reduced the flow of blood; the cellular and fluid exudate pressed on the nerve cells and fibers. In this way alone disturbance of function leading to paralysis of muscle groups might be produced. This class of pathological changes was subject to complete reversion. Once the infectious process was arrested, as it was by the developing immunity principles, resolution of the exudate occurred and function was restored. This change was noted clinically quite frequently in cases in which paralysis of members disappeared in a few days or weeks. But another severer lesion might occur. The virus of the disease might attack and severely injure or actually destroy nerve cells. When the cells of the anterior horn were thus injured and became neuritic, they were quickly invaded by phagocytes which brought about their disintegration. This process was not reversible; its effects were therefore permanent. Commonly the two classes of changes were united in one person, so that partial, but not complete recovery of function took place. The muscles presided over by the lost nerve cells were, of course, for the time being paralyzed. The theory on which Dr. Lovett was proceeding in this instance was to reeducate the nervous system in such a manner as to open new paths along which impulses might pass from the brain to the muscles. On account of the many connections between neurons, there would not seem to be anything anatomically impossible involved in the concept. The proof must lie in the results achieved by the educative methods which he described. In concluding, Dr. Flexner called attention to the fact that the pathological processes, being what they were, tended to reversion. Hence recovery was the outcome to be looked for and expected, its extent being determined by the degree of the reversionary process to which the paralysis was due. Hence any form of treatment not distinctly prejudicial would be followed inevitably by some improvement. This improvement tended to occur during the early weeks or months following the attack; the paralytic residue, after this process was exhausted, was that attributable to severer injury or destruction of nerve cells. The restoration of this further loss of function, when it was accomplished, might be the result of the reeducative methods which had been described.

Dr. EDWARD C. ROSENOW said that Drs. E. B. Towns, G. W. Wheeler, and himself had studied the present epidemic, both in Rochester, Minn., and here in New York at the New York Hospital, from the standpoint of the elective localization of bacteria from the tonsils and throat and from lesions in the central nervous system. The technique used was similar to that employed by him in studies on the elective localization of bacteria in various other diseases, including diseases of the nervous system. They had found in the tonsils, especially in patients over three or four years of age, a surprisingly large amount of infective material, though these patients showed none of the subjective or objective signs of tonsillitis. In all of seventeen cases in which the tonsils were removed after death and carefully sectioned there were found from one to fifteen abscesses, usually at the base along the capsule, but not communicating with the surface. They contained a peculiar opalescent material containing large and small mononuclear cells, polymorphonuclear leucocytes, and often large numbers of diplococci of the usual size; occasionally there were some small forms, fusiform bacilli and micrococci. Adenoids removed from four patients at autopsy showed similar abscesses. The ages of these patients ranged from seven months to twenty-four years. Owing to the presence of large numbers, and often in almost pure form, of a streptococcus which produced paralysis in animals, rabbits, guinea-pigs, dogs, cats, and monkeys, and to the low virulence of the bacterial flora in these patients, they felt with Dr. Roper that tonsillectomy was justified in those patients in whom there was persistence of fever, irritability, lack of appetite, and little or no improvement in the paralysis, or those in whom the paralysis was slowly extending. This had been done under light anesthesia in eleven cases, and in no instance was there any sign of acute tonsillitis. In most of them a large amount of pus and cryptic material was found during the tonsillectomy. Numerous cross-sections of the extirpated tonsils revealed pockets similar to those found in the tonsils in the fatal cases, but which were smaller and fewer in number. None of the patients were made worse by the operation; indeed, most of them showed improvement soon after the tonsillectomy, and in several instances the results were strikingly favorable. In the light of these facts it was possible that unrecognized foci in the lymphoid tissue of the throat were an important factor in determining the severity of the initial paralysis and especially in preventing the usual early improvement. The localized foci probably afforded the entrance way of the organisms having an elective affinity for the central nervous system. The number of cases in which tonsillectomy was performed were, of course, too few to warrant the drawing of positive conclusions, but they were highly suggestive. The experiment had proved, however, the presence in the throat, in the tonsils, and in the central nervous system, in epidemic poliomyelitis of a peculiar streptococcus which produced in animals a flaccid paralysis similar to that observed in patients afflicted with poliomyelitis.

Dr. FREDERICK TILNEY said they were greatly indebted to Dr. Lovett for showing them what could be done in the after-care of this disease. There were certain details which interested him particularly. It was well known that there was a focus of intensity of inflammatory activity in the central nervous system, and that this determined the degree of paralysis. They had no means at the present time of combating the inflammatory process in this focus in the acute stage of the disease. It might be that serum did some good, and experience seemed to show that it was of some benefit in the preparalytic stage and in the ascending, bulbar, and meningitic types of the disease. The first thing was to determine where the focus of inflammation had been in order that the muscles most affected might receive attention. With electric reactions this might be shown best, and the electric reaction should be taken at the outset in every case since it was not only important in di-

agnosis and prognosis but equally so in treatment. Some said that active treatment should begin when acute symptoms disappeared; others that it should begin six or eight weeks after the onset. The disappearance of tenderness was the best guide as to the time when it was advisable to institute treatment. This might occur by the end of the fourth week, but if tenderness still persisted treatment should be deferred. The usual forms of treatment (immediate after-care, not surgical treatment) were exercise, electricity, massage, and support. Electricity seemed to have fallen into disrepute because some had obtained poor results, but it should be remembered that in many instances electricity had been applied unscientifically; sometimes but one battery had been used at home by the patient. The faradic current should not be used, for it was absolutely of no use in the case of profoundly paralyzed muscles and it partially tetanized paralyzed muscles, which was exceedingly fatiguing. The most beneficial type of current was the sinusoidal, and this could be used to advantage provided certain details were observed. It should not be applied unless the limb was first massaged and heated by means either of a hot pack or the calorescent lamp; otherwise the contraction of the muscles caused by the electricity was painful. At the end of three or four weeks one could begin to give warm baths to which a considerable amount of salt had been added. While the patient was in the bath voluntary movements might be attempted which would be assisted by the buoyancy of the salt water. Efforts directed toward the reeducation of the muscles might be begun as soon as the patient could get up and about; this was usually about the fifth week. There should be individualization in the muscle reeducation and the treatment should be carried out at stated intervals every day for a long time. Braces, splints, plaster casts, etc., carefully and properly applied, were indicated when a limb was in malposition or when a paralyzed muscle was unduly stretched, and this treatment should in every instance be combined with the use of electricity, massage, etc. These various means constituted the type of treatment that every case was entitled to, and without such a combination of treatment and its persistent application for a long period of time no child could be said to have had a full opportunity for completely normal restoration.

Dr. Charlton Wallace said the medical profession owed much to Dr. Flexner and his associates for what had been taught them regarding poliomyelitis. All who had children had been afflicted during the past few months with hysteria because of this disease which they did not know how to control. He had nothing to say about the pathology and histology of the disease, but would confine his remarks to the treatment. Each case of poliomyelitis presented its own problem and was an individual study. A prerequisite for the proper care of these cases was a knowledge of muscular anatomy and mechanism. It was well to beware of those who were not properly trained in anatomy and the mechanism of the muscles. Treatment was to be considered when the acute stage stopped, but there was no telling how long the acute stage might last; it lasted as long as the acute inflammatory process in the spinal canal continued, and this was as long as there existed any tenderness in the joints. There should be no treatment during the acute stage, unless to prevent toe drop, except the serum treatment. After the acute stage orthopedic treatment should be instituted. Dr. Wallace said that some cases had come under his observation in which the tenderness persisted for three or four months, and in these cases the patient should be kept in bed. A bed suitable for a patient with paralysis of the shoulders and back muscles should have no springs, but should consist of a mattress on a wooden platform, so that there should be no sagging, the aim being to keep the body as well as the extremities in a horizontal plane. It was important that orthopedic treatment be supplemented by general hygienic care, and this was the duty of the family physician. If anything was to be said about braces it would be to disagree with what had been said, for in his opinion no patient having had poliomyelitis should be allowed to go about without braces. The brace was to prevent deformity and to avoid the stretching of weak muscles and so that the pull of strong muscles would not produce contractures. Walking should be encouraged as soon as the patient could stand and get about, as it trained the muscles to functionate again. Dr. Wallace said they owed something to Dr. Teschner for an article published in the *Annals of Surgery* of November, 1899, in which he advised muscle training, but warned that it would not cure a patient, but was simply an aid toward restoration of power. In some cases coming under his experience in which muscle training had been employed and parents had been led to believe it would do all the work, the deformity which resulted had been the greatest he had ever seen; there had been the most severe lateral curvature after this treatment. Therefore if one used muscle training it must be done with the greatest care and caution and support should be used where it was needed. One should take advantage of every aid that could be used in treating these patients without permitting oneself to be misled in regard to anything. Operative treatment should not be undertaken until four or five years had passed except to correct contractures and deformities. Where there was a dangling foot it might perhaps be operated on in from two to two and one-half years after the onset of the disease. The removal of the astralagus and the displacement backward of the foot, combined with the transplantation of active tendons, was the procedure used in this condition. Several cases coming under his observation had been helped by comparatively early operation; they were less troubled by cold and frostbite in the winter. Frostbite which had occurred before the operation did not recur the winter following the operation. In patients who seemed to have no calf muscle at all he had seen the calf muscle develop under treatment. With proper braces, proper care, and persistent treatment one might get improvement if one was patient and could control the parents and persuade them to wait and watch.

Dr. Godfrey R. Pisek said he begged to disagree with Dr. Lovett in his statement that he was presenting nothing new this evening. We must acknowledge that his scientific method of muscle testing would add valuable facts to our conceptions of poliomyelitis and place the treatment on a more rational basis. Dr. Lovett brought a glad note of optimism—an optimism based on results obtained and recorded. As one of the jury listening to his statistics Dr. Pisek said he would vote that Dr. Lovett had proved his case. Dr. Wallace had discussed this paper from the orthopedic standpoint; he wished to take this opportunity to say a few words on the duty of the pediatrist. The pediatrist was mainly concerned with the acute and convalescent stages, and it would seem that upon him devolved the task of sifting out the large mass of data gathered during this epidemic, particularly from the clinical standpoint; establishing, if possible, a symptomatology for the acute stage. Seventy per cent. of the cases were easy to diagnose; the other 30 per cent. were not so readily diagnosticated, while the so-called abortive or nonparalytic types were baffling in the extreme. Another duty that was before them was the analysis of the great number of cases observed in the city, so that they might have a rational basis for their treatment. The laboratories were at work and some were offering new etiological factors that certainly opened up new avenues of thought. The serum treatment, except in the very early hours of the disease, had lost the support of those who used it with great hope and who had the largest opportunity to watch its effects. Dr. Roper reported for the New York Hospital Annex that there were no drugs whatever used, nursing care only being employed (except in one case of serum treatment), and yet in this hospital the mortality was lower than that reported for the city. The specific treatment must wait upon the pathologists and epidemiologists, but meanwhile the management must be worked out in relation to the pathological processes of repair and absorption which took place even after the infection had occurred. Emphasis should be placed upon the counsel of the essayist—precision, efficiency, and persistence in the treatment. The public, owing to the courageous stand of the Health Commissioner, had been awakened to their responsibilities. The orthopedic institutions of the city would not have room efficiently to care for the large number of cases discharged from the hospitals. The ordinary dispensary was not fitted or qualified to do so. There was need for immediate action on the part of the Association of Outdoor Clinics to the end that a uniform standard of equipment might be established, that follow-up work be enforced so that the patient might be constantly encouraged, and the necessarily long course of treatment, as Dr. Lovett had so admirably shown, might be persisted in, restoring to usefulness many who would otherwise remain crippled for life.

Dr. Foster Kennedy said that there was nothing that had not been said better than he could say it. Dr. Lovett spoke of the attitude of the neurologist and of balancing the advantages of the brace and electricity. There could never be an even balance, because electricity at its worst was not much more harmful than an

incantation while braces could be destructive. Neurologists for years had striven against the splinting of palsied legs. If a rigid apparatus was placed on a muscle that already had a damaged innervation it made that muscle more atrophic and recovery more difficult. Passive movements and massage constituted proper treatment, but when given only two or three times a week they were useless. It was only reasonable to give them for five or ten minutes five or six times a day. If the mothers were taught in the dispensaries how to give this treatment better results would be obtained among the children of the poor than among the children of the rich who received treatment at less frequent intervals. Dr. Kennedy said he spoke only to emphasize the convictions of most neurologists as to the best means of getting results in these cases and to urge the necessity of continued massage and passive movements for a long period of time and many times a day. If this was carried out there would be less deformity and fewer braces, and still fewer operative procedures would be required.

Dr. Abraham Jacobi said that he had seen this disease occasionally for the past sixty years and what he had heard about it to-night had not been at all uniform. He had not seen any cases during the epidemic this summer, but had seen a number of cases in the epidemic of 1907. He thought the disease as it appeared in sporadic cases was about the same years ago as at the present time. The cases usually had the following description: A baby was put to bed apparenty well and was taken up in the morning paralyzed, with from two to four sets of anterior spinal nerves involved. The course of the disease, as a rule, was as follows: The child was badly paralyzed at first; it was better in five or six days. The improvement during these first days was rapid, then less rapid for five or six weeks, and that was the end of the improvement. One case coming under his observation was an exception to this; in this case the child was treated by the galvanic current, some 600 or 800 applications having been made over a period of years. This child finally got well. Dr. Jacobi said that if he had anything to say about the treatment of this disease it was that one should not undertake any form of treatment unless it could be extended over a number of years.

Dr. Herman C. Frauenthal said that in the application of electricity, the massage oil or talcum must be removed before the electricity was applied. To be successful with electricity the galvanic current must be used. The faradic current was not definitely standardized and the sinusoidal was not to be depended upon. The galvanic current always gave contraction in an increasing or decreasing amount and it was the only current that could move muscles that were partially paralyzed. All currents had a value in the hands of the man who understood their effects. Muscle training could not be applied until the child was about three years of age. A good way to reeducate muscles was to have the child make a movement with the normal limb and then to endeavor to imitate it with the affected limb.

Dr. Lovett, in closing the discussion, said he had been much interested in the free discussion and in the different opinions expressed. He felt, however, that at the present time the situation was such that it was better to emphasize the matters upon which they could agree than those upon which they differed.

THE AMERICAN ASSOCIATION OF IMMUNOLOGISTS.

Third Annual Meeting, Held in Washington, D. C., May 11 and 12, 1916.

(*Concluded from page 657.*)

Immunity Results Obtained from the Use of Diphtheria Toxin-Antitoxin Mixtures and the Use of the Schick Test.—Drs. William H. Park and A. Zingher of New York City presented this paper, based upon a series of over one thousand cases, that had been actively immunized with diphtheria toxin-antitoxin. These susceptible individuals were selected by means of the Schick test out of a total of about 10,000 children and adults in 10 different institutions. The mixtures of toxin-antitoxin that were used for immunization were either neutral (66-70 per cent. L + to each unit of antitoxin) or slightly toxic (80-90 per cent. L + to each unit of antitoxin) to the guinea-pig. The dose was varied from 0.5 c.c.-1.0 c.c., and the number of injections from one to three. The injections were made subcutaneously at intervals of 7 days. The local reactions at the site of injection were generally mild; in the older children and adults, the redness and swelling were more marked. General symptoms, like malaise, and temperature of 100°-102° F. were noted in 10 to 20 per cent. of the cases; in a few the temperature reached 104° F. The symptoms lasted 24 to 48 hours, and then rapidly subsided. Both local and general symptoms were especially evident in those who showed a susceptibility to the protein by giving a combined pseudo and true Schick reaction. No harmful after effects were noted in several thousand injections. The retests with the Schick reaction showed that only 30-40 per cent. became immune 3 weeks after the first injection, about 50 per cent. at 4 weeks, 70-80 per cent. at 6 weeks, and 90-95 per cent. at 8 to 12 weeks. The best results were obtained with the full immunization, consisting of 3 injections of 1.0 c.c. each, given at weekly intervals. The duration of the active immunity was studied in a group of children that were followed up for over 1½ years; these cases showed that the active immunity persisted for at least that length of time. It is possible, that the immunity induced by the injections of toxin-antitoxin started a continued cellular production of antitoxin, which would have otherwise appeared much later in life. From their results Park and Zingher concluded that it was advisable to immunize children soon after the first year of life, so as to afford them a protection against diphtheria at a time when the disease was most dangerous. In addition such young children, by not having any hypersensitiveness to the bacillus protein, showed very mild local and constitutional symptoms after the injections. An immune child population could thus be developed with the result that fresh clinical cases would be prevented and the bacillus carrier would probably soon disappear as a hygienic factor in our communities. Interesting and parallel results were noted in guinea-pigs and horses. Guinea-pigs were fairly resistent to active immunization with diphtheria toxin-antitoxin, and in that respect they showed an almost complete parallelism to the positive Schick cases among human beings. After injections of toxin-antitoxin, an antitoxic immunity developed slowly from the 6th to 8th week. Horses, on the other hand, as a rule corresponded in their behavior toward small doses of toxin-antitoxin to human beings, who were naturally immune. They both gave a ready response, even after a single injection of toxin-antitoxin, and showed a distinct increase in the antitoxin content toward the end of the first week. Occasionally, a horse was found that had no antitoxin in the control bleeding; such animals responded slowly to small doses of toxin-antitoxin. It was probable that the tissue cells of the naturally immune human beings and the majority of horses had acquired the property of giving a quick and easy response to the stimulation of diphtheria toxin. The use of the Schick test in the selection of susceptible children for immunization and in controlling the results of the treatment was justified by the great clinical accuracy which the test had shown during a period of several years in the separation of the susceptible from the immune individuals. The test should be carried out properly with a fresh toxin solution, and the results read daily, for a period of 72-96 hours. The pseudo-reactions should be controlled with heated toxin, or recognized by their rapid disappearance after 72 hours. It was only those individuals who gave the more marked local reactions after the injections of toxin-antitoxin. In conclusion Park and Zingher stated that the Research Laboratory of the New York City Department of Health would supply those who were connected with institutions, and interested in taking up the work, both the toxin for the Schick test and the toxin-antitoxin for immunization.

Anaphylactic Food Reactions in Dermatology with Special Reference to Eczema.—Dr. Albert Strickler of Philadelphia spoke of the relation of diet to various diseases of the skin. Fourteen food products were tried out. The method of injection employed was the endermic one, and the dose used was one-tenth of a c.c. In all, four diseases were studied—eczema, urticaria, acne and psoriasis. In conclusion, he said the anaphylactic food tests were of value in the etiologic diagnosis and in the treatment of various diseases of the skin. These reactions found their greatest value in eczema. In chronic urticaria, acne and psoriasis the tests were disappointing. As yet our experience was too limited to draw any definite conclusions.

Comparative Studies of the Wassermann and Hecht-Weinberg Reactions in Syphilis, with Special Reference to Cholesterinized Antigens.—Dr. JOHN A. KOLMER of Philadelphia stated that the Hecht-Weinberg test utilized the complement and natural anti-sheep hemolysin of the human serum. The primary object of this study was to determine if this test was more delicate than the Wassermann reaction conducted with cholesterinized extracts. The Hecht-Weinberg tests were conducted after the modification of Gradwohl, by which the hemolytic activity, and accordingly the proper dose of sheep cells to be used for each serum, was determined according to the amount of a 5 per cent. emulsion of sheep cells hemolyzed by a 0.1 c.c. of serum. The same three extracts were used in the Hecht-Weinberg and Wassermann tests, namely, an alcoholic extract of human heart reinforced with 0.4 per cent. cholesterin; an alcoholic extract of syphilitic liver, and an extract of acetone insoluble lipoids of beef heart. All extracts were titrated for the antilytic and antigenic units in both systems, respectively. With sera collected twenty-four to forty-eight hours previously, 93 per cent. were found to contain sufficient complement and anti-sheep hemolysin to permit the conduct of the Hecht-Weinberg test. In 82 per cent. of the sera the results varied and in this manner: in 15 per cent. the Wassermann was negative and the Hecht-Weinberg test positive. Of these reactions, the positive Hecht-Weinberg tests were largely correct and occurred mostly with the sera of syhilitic persons under vigorous treatment; in 3 per cent. the Wassermann was positive and the Hecht-Weinberg was negative, and all of these occurred with the sera of persons in the latent and tertiary stages of syphilis. With the sera of persons known not to be syphilitic, the Hecht-Weinberg test showed about 10 per cent. falsely positive reactions; most of these reactions occurred with the alcholic extract of syphilitic liver, and fewest with the extract of acetone insoluble lipoids. All of these sera yielded negative Wassermann reactions with all antigens. The Hecht-Weinberg test was found unreliable in the diagnosis of syphilis on account of the tendency to yield proteotropic reactions; it was more delicate, however, than the Wassermann test, and had its greatest value in a negative reaction as a control on treatment with the sera of known syphilitics. In conducting the Hecht-Weinberg test, alcoholic extracts of syphilitic liver were found least, and extracts of acetone insoluble lipoids best suited for this technique.

Studies in the Epidemiology of Lobar Pneumonia.—DR. A. R. DOCHEZ of New York presented this communication. He said studies had been made of pneumococci isolated from individuals suffering from lobar pneumonia and had shown that the majority of these organisms fell into definite biological groups. In view of these constant differential characters of the pneumonococcus, it had been deemed advisable to study the pneumococci occuring in normal mouths. It had been commonly assumed that infection in pneumonia was autogenic, and occurred from invasion of the lungs by pneumococci habitually carried in the mouth. If this was so one would find the same types in the normal mouths that occurred in disease. Examination of a series of normal individuals showed this not to be the case. The two types of pneumococci responsible for the majority of severe cases of lobar pneumonia were not found in the normal healthy mouth, except in such instances as where the individual harboring of the organism had been in intimate association with a case of lobar pneumonia. When such a condition existed, the organism found in the normal mouth invariably corresponded in type to that found in the lung of the diseased individual. These studies made it probable that the majority of cases of pneumonia were dependent either on direct or indirect contact with a previous case.

CAPTAIN EDWARD B. VEDDER of Washington, D. C., said they had thought for a number of years that they knew all about pneumonia. They had learned a long time ago that perhaps a large proportion of normal individuals carried the pneumococcus in the sputum. Of course, it was plain that if they suddenly became chilled and their resistance was greatly lowered that they would develop pneumonia. This was a very comfortable theory. This was nobody's fault and they did not have to do anything about it except to die when their turn came without making too much fuss. Now, Doctor Dochez and his associates came along and told them that this was like other things they had learned; it was all wrong. Now, if Doctor Dochez was right, and the speaker was inclined to think that he was, the question was "What were they going to do about it?" Treatment with the anti-pneumococcic serum seemed to be a little discouraging in view of the fact that it would be a long time before the practicing physician would recognize the different types of pneumococci as he ordinarily met them. This was a difficulty that could be obviated by co-operation with the laboratories. But this entailed delay. In any case, prevention was much more important than cure, and it was right here that Doctor Dochez's paper opened up a most hopeful vista. It meant that every case of pneumonia might be traced directly to a previous case, either directly or indirectly. It meant that from a sanitary point of view pneumonia must be treated just like any other infectious disease in which the infecting agent was transmitted by the buccal secretions of those affected, and that the present widespread prevalence of pneumonia was due to the present policy of *laissez faire*. When the various boards of health finally came to life, as they probably would in from one to twenty years, they might expect the following measures: (1) Notification of all cases of pneumonia. (2) Prompt visitation by a health officer, collection of specimens, and laboratory diagnosis of the type of organism present, in the patient and in the contacts. (3) Isolation of the patient and of any contacts who harbored the type of pneumococcus found in the patient. (4) A negative culture requirement before the patient or carriers were permitted to mingle with the community.

The Localization of a Streptococcus in Animals from a Case of Recurring Neuritis and Myositis.—Dr. EDWARD C. ROSENOW of Rochester, Minn., presented this contribution which he summarized as follows: A streptococcus having peculiar properties was isolated from the dead pulp of the left upper first molar in the region where the attacks of pain usually began. The streptococcus was also demonstrated in the sections isolated from the infiltrated deep fascia and muscles of the left side of the neck. A similar streptococcus was isolated from the pharynx and stool. This streptococcus was proved to have elective affinity for the pulp of teeth, dental nerves and muscles in animals. It was repeatedly isolated from and demonstrated in the experimental lesions in animals whose blood was sterile; the lesions were again produced on injection and the streptococcus again isolated. Many animals appeared to be in pain, and one rabbit had marked swelling and tenderness over the left upper jaw. This affinity was proved absent in the diphtheroid and *B. fusiformis* also isolated from the pulp of the tooth, and in the streptococcus broth culture filtrate. Streptococci from other sources rarely caused lesions in the pulp of teeth and dental nerves. The phagocytic power of the patient's blood following the attack over the strain from the tooth was twice that of comparable normal blood. These results would appear to warrant drawing the conclusion that the attacks of pain in the face in this patient were due to a streptococcus infection of the sheaths of the dental nerves, and that the pain, swelling, tenderness and spasm of the mucles of the neck were due to myositis and fibrositis—the result of infection by this streptococcus. The demonstration of living streptococci in the pulp of the tooth and in the fascia of the muscle during quiescent intervals was significant, and might explain the recurrence of the attacks. The cavity in the tooth containing the dead pulp originally infected from the mouth, judging by the character of the filling and the bacterial flora, was quite unable to heal for mechanical reasons. This appeared to afford a culture medium for the growth of the streptococcus. From stimulation of the defensive mechanism in the patient during the attacks, active growth appeared to be held in check and the symptoms disappeared in consequence, only to reappear later from recurrence of active growth and localization of the streptococci when immunity was low. The improvement in the condition of the patient since the extraction of the tooth appeared to be due to the removal of this focus and to prolonged artificial stimulation of the defensive mechanism by means of the autogenous vaccines, which it was hoped would lead to the destruction of all the streptococci in the muscle and dental nerves, and result in the ultimate recovery of the patient. However, the isolation of the streptococci from so many places would probably make recovery difficult.

DR. GEORGE W. WHEELER of New York stated that streptococci were usually classified according to their

effects in bloodagar plates, as hemolytic or non-hemolytic. The non-hemolytic varieties had been further classified according to their fermentation reactions with different sugars, but wide variations were found by these methods, due to the variations in the organisms themselves and to chemical changes in the sugars during the process of sterilizing the media. None of these differential methods gave any clue as to what the streptococci would do when they were in the animal body. Doctor Rosenow's work began where these methods ended. His original idea was that organisms growing in the human body had certain delicate, transient, biological activities which were soon lost when the bacteria were grown on artificial media. In order to demonstrate these activities, the organism must be transferred from the human organism to animals, the original culture from the patient being used for inoculation, and the lesions in these animals studied. Animal inoculation with recently isolated brains, grown under certain definite conditions, showed that the lesions produced in the animals were very often similar to those in the patient from whom the organisms were obtained. Whether this was merely a coincidence or a specific affinity which the organisms had for certain tissues could only be determined when a great deal of experimental evidence of this kind had been presented and carefully examined. Control animals were necessary to rule out the possibility of the lesions being spontaneous. In work which he had done according to the methods described by Doctor Rosenow, with streptococci from nine cases of arthritis and endocarditis, lesions were found in the joints of animals in 75 per cent. of the cases; in muscles in 63 per cent.; in the heart in 55 per cent., while in other organs lesions were relatively infrequent; the appendix, 6 per cent.; the stomach, 11 per cent.; the brain and cord, 6 per cent.

Dr. E. C. Rosenow of Rochester, Minn., in closing the discussion, said that he preferred using the terms "green producing" and "hemolyzing streptococci," instead of streptococcus viridams and hemolytic streptococcus, because there appeared to be numerous variants of each strain, particularly of the former, and because one might be transmuted into the other. He expressed his appreciation of the work done at the Rockefeller Institute on the classification of the pneumococci and the observations made on them. In his hands the pneumococci showed, as in those of Doctor Cole and Doctor Dochez, fixed characters when grown in the usual way, but when the pneumococci were placed under special environment they lost their specific glutinating reactions and took on new features, and they might be converted even into hemolyzing streptococci. The demonstration of living streptococci in the muscles during the quiescent period was of importance and in accord with similar findings in ulcer of the stomach, chronic rheumatism, cholesystitis, etc., because it showed that not too much should be expected from the removal of the primary focus in these diseases which were characterized by exacerbations and quiescent intervals, and served to explain these exacerbations and remissions.

A Note Concerning the Specificity of Pneumococcus Types. — Drs. A. P. Hitchens, E. K. Tingley, and George Hansen of Glenolden, Pa., reported this case. They stated that the horse in question had been under treatment for several months with a pneumococcus corresponding in serological reactions with Neufeld type 1. The last injection was given about one month before death, and the bleeding subsequent to this showed that the potency of the serum of this horse was such that 1,100,000 c.c. of the serum would protect a mouse against a fatal dose of pneumococci of the homologous type. Blood culture three days before the death of the horse showed the presence of a pneumococcus not corresponding in type with that with which the animal had been injected. The pneumococcus recovered was still under examination. It did not correspond with type and was not the mucosus. It did, however, bear strong resemblance to some strains of pneumococci obtained from equine infections. Autopsy of the animal showed pulmonary consolidation and inflammation of the mucous membranes lining the respiratory passages.

Studies in Typhoid Fever.—Dr. A. L. Garbat of New York presented this contribution. He first considered the complement fixation test after prophylactic immunization and compared it with the agglutination test. As a result of these investigations, he makes the following summary: In contrast to the strong agglutination test a positive complement fixation test after prophylactic typhoid immunization was not a regular occurrence, as it was during or after typhoid fever. This point might be an aid in deciding for or against the diagnosis of typhoid fever in an inoculated individual still having a positive Widal and ill with a suspicious typhoid and negative blood culture. A positive complement fixation test was obtained most often after three injections with a polyvalent vaccine; two injections with this same vaccine or three injections with the single strain (Rawling) gave hardly any complement fixation. He presented a study of duodenal cultures in typhoid fever. He stated that of every 10,000 apparently perfectly healthy residents 2.3 per cent. were typhoid carriers and that 55 per cent. of all typhoid cases were due to carriers, either directly or indirectly. Of every 100 typhoid cases three to six became carriers. This made it evident that the ideal prophylaxis in typhoid fever was the detection of the typhoid carrier. A questionnaire sent to various hospitals for the purpose of finding out what and how many institutions examined the urine and stools of their typhoid patients before discharging them showed that of twenty-four institutions nine examined the urine and stools before discharging patients; eleven institutions disregarded such examinations entirely. There were many difficulties which they all had with the stool examinations. For this reason the writer had devised a method of collecting bile from the duodenum by means of the Einhorn duodenal tube. He had found that this was a simpler and more reliable method for the detection of typhoid bacilli than stool examinations.

Doctor Garbat presented a third study with reference to convalescent typhoid serum in the treatment of typhoid fever, based on his experience with three cases. All three cases were very acute, and in all the serum from convalescent typhoid patients had been employed with distinct benefit. The writer believed it was worth while to try this form of serum therapy.

Dr. A. H. Sinclair of Honolulu, Hawaii, said he was prone to believe that, after the use of typhoid vaccine, if typhoid fever occurred, there must have been something wrong either with the vaccine itself or with the technique of its employment. He did not believe that any patient who gave a positive Widal after typhoid fever could again contract the disease. The isolation of the bacilli from the blood or from the stools showed the applicability of the complement-fixation test.

Dr. George H. Robinson of Glenolden, Pa., related an experience with a small number of cases of typhoid fever, in which it seemed that clinically the well-fed cases gave fewer typhoid carriers than the starved cases.

Dr. Abraham Zinger of New York said that during the past eighteen months at the Willard Parker Hospital he had been giving convalescent fresh whole blood by means of intramuscular injections in scarlet fever cases. Distinct benefit was noted in toxic cases after injections of blood obtained from patients who were three to four weeks convalescent. If it should be proved that convalescent blood had therapeutic value even as late as six months after the disease, then the opportunity of employing this treatment would be much greater. Convalescent blood could be used not only in diseases that resulted in a more or less permanent immunity, like scarlet fever, typhoid and measles, but also in diseases that were followed by only a short protection, like ervsipelas and pneumonia. The blood in these cases should be obtained from donors not more than two to three weeks convalescent. Doctor Zinger said he had used intramuscular injections of normal blood in late septic cases of scarlet fever, in which the toxemia was no more in evidence. Such blood was not given for any specific action, but for its general stimulating and nutritive value.

Doctor Garbat, in closing the discussion, said that all the cases at the German Hospital were fed by the high caloric method; the physicians had practically abandoned the starvation treatment. Whether typhoid carriers occurred more frequently in those with high caloric value or in these under the so-called starvation treatment he did not know.

Friday, May 12—Second Day.

The Standardization of Antimeningitis Serum by Animal Protection Tests. — Dr. George H. Robinson of

Glenolden, Pa., presented this paper. He stated that the variable ability to produce agglutinins and complement fixing bodies had been noted among horses under antimeningococcic treatment. An animal protection test seemed desirable as a measure of the potency of the serum. A sixteen-hour old culture of meningococci on serum dextrose agar was necessary for the test. Suspended in fresh guinea pig serum and diluted three times with 0.85 per cent. salt solution most strains were virulent for white mice. If antimeningococcic serum was injected two hours previous to the infection of the cocci, considerable protective power could be demontrated. The amount of serum used had been invariably 0.5. Culture was used in 0.5, 0.25, 0.12, etc., amounts. By this method the amount of protection afforded by different sera very closely paralleled the extent of the treatment the horses had received. Agglutinating and complement fixing powers showed no correlation with protective power. The test was specific in that different strains of meningococci could be distinguished as well as the gonococcus. As a routine measure all freshly isolated strains of meningococci were tested with a polyvalent serum, and those against which the serum did not protect were incorporated into the treatment of the horses. The polyvalency of antimeningitis serum was of extreme importance. If the amount of immune serum necessary to protect against one minimum lethal dose of living culture be considered as a unit, a uniform standardization of antimeningitis serum was obtained. Such a standard meant more to the physician, and was a better test of the therapeutic efficiency of a serum than test *in vitro*.

An Analysis of a Series of Cases Changing to Wassermann Positive after a Negative Period of Twelve Months or Over. — Dr. LOUIS A. LEVISON of Toledo presented this report. He said he had collected sixteen cases fulfilling the conditions mentioned in the title. Six of these patients had been treated at least in part by the writer, and of these only one was treatd from the start. The idea that a single negative Wassermann after treatment meant a cure of syphilis was entertained by many physicians despite its utter lack of basis in fact. The cases cited showed that a patient with syphilis might not be cured or have his disease process arrested even after the Wassermann had been negative for twelve months. There was more than passing significance in the fact that practically all these cases were late or advanced when they were competently treated. They received mercury either in small or inefficient amounts, some not at all, at the time when treatment could have been of value. The Wassermann reaction had a definite value as a guide to treatment, but care should be taken in dismissing a patient from treatment and observation on the strength of a Wassermann negative period which had not lasted longer than from twelve to eighteen months.

A Stable Bacterial Antigen with Special Reference to the Meningococcus Antigen. — Dr. GEORGE HANSEN of Glenolden, Pa., presented this communication. He stated that various methods had been recommended for the standardization of antimeningococcus serum. No method so far devised was considered satisfactory. There had recently been a return to the complement fixation, not because it was supposed that complement fixing antibodies had any exact relationship to the therapeutic value of the serum, but because the method was fairly accurate and served to identify the serum with the various types of meningococci with regard to polyvalency. An antigen, which might be distributed to various laboratories, and which would remain unchanged under the varying conditions therein, would remove one source of variation in results. Furthermore, such an antigen might have great value in the case of other bacteria, as for instance, the gonococcus. Cultures for the preparation of dried meningococcus antigen were grown on salt free agar. The growth was collected in distilled water, an equal volume of alcohol was added and the mixture centrifuged at high speed. The bacteria was further dehydrated by repeated washing with alcohol and finally with ether. The resultant mass was dried and preserved *in vacuo* over phosphorus pentoxid. For use weighed amounts of antigen were ground in a mortar and suspended in physiological saline solution. The usual preliminary titrations and controls were set up to be certain that the reactions were specific. The dried antigen had been checked up against its homologous serum and a large number of heterologous sera and had been found to yield specific results.

The Clinical Significance of the Wassermann Test. — ARTHUR F. COCA of New York, read this paper. He said the Wassermann reaction was a biochemical test; that as it was performed with reagents whose chemical constitution was practically unknown, some of them being relatively very unstable bodies. The Wassermann "mixture" was subject to considerable variations dependent upon the particular method or modification of the original technic used and also upon the manner of standardizing the different reagents, as well as upon the quality of the antigen preparation available. On account of the above mentioned technical variations as well as on account of factors heretofore uncontrolled a considerable want of uniformity in the results of the Wassermann test existed. There had yet to be recorded a series of parallel tests carried out by different observers on the same sera in which the results agreed throughout. As had been pointed out by Uhle and MacKinney, the disagreements were more common in just the cases in which the need of reliable information was greatest. The results of the Wassermann test were further vitiated by the fact that it was being performed by an ever-widening circle of superficially informed and uncontrolled "techicians." It had been clearly demonstrated that the positive Wassermann reaction was not specific for syphilis. It occurred not only with some regularity in other conditions, but also sporadically in many others. Analysis of its relations to the therapeusis of syphilis showed that in the great majority of instances the result of the test did not influence the course of specific treatment. The use of the Wassermann test as a legal criterion of eligibility for marriage must be unconditionally opposed.

Serum Reactions Following Treatment with Sensitized and Non-Sensitized Bacteria.—Dr. G. H. SMITH of Glenolden, Pa., presented this contribution. He stated that work he had been doing toward the determination of the mode of reaction induced by immunization with sensitized and non-sensitized typhoid antigens gave the following results: (1) The agglutinating titre of the sera obtained indicated that the non-sensitized antigen was more efficient. The difference, however, was slight. Agglutinins appeared earlier in the course of the treatment if a non-sensitized antigen was used. (2) Sera produced by treatment with non-sensitized antigen were more active in complement fixation tests. (3) In the case of the opsonic and bacteriotropic indices the differences in values obtained were not of great significance, either in degree or in the rate of production. (4) The degree of leucocytosis produced with the two types of antigen indicated an essential difference. The animals receiving sensitized antigen responded with a greater production of leucocytes, the response after each injection being increasingly greater, and the increase occurring after a shorter interval of time than in the animals receiving non-sensitized antigen.

Prophylactic and Therapeutic Inoculations in Certain Affections of the Respiratory Tract.—Drs. GEORGE W. ROSS, H. K. DETWEILLER and J. C. MAYNARD of Toronto presented this communication, in which they express the opinion that so-called "common colds" might be due to a variety of microorganisms, such as the *B. rhinitis*, *B. influenzae* of Pfeiffer, *M. catarrhalis*, the pneumococcus and various streptococci. The question arose as to the likelihood of symbiosis occurring among these organisms, increasing their parasitism. There was recently an epidemic of "cold" in Toronto, during which a whole batallion of soldiers quartered there were unfitted for duty because of this epidemic. The writers prepared vaccines from many strains of different organisms isolated. Sixty-two soldiers were inoculated with these vaccines, receiving from one to six inoculations. The results were very gratifying, and warranted the suggestion that this method might at least be applied to the control of such epidemics in institutions where large numbers of people were in close contact.

The Diagnosis and Treatment of Septicemia. — Dr. OSCAR BERGHAUSEN of Cincinnati read this paper. He said the essential feature of septicemia was the multiplication of infecting organisms within the blood current. The termn "bacteriemia" was not descriptive of any special pathological condition. It would be far simpler to speak of infections due to ordinary organisms of suppuration, as either "toxemia" or "septicemia," meaning by the latter term that the organisms had begun to multiply in the blood current. Pyemia was simply a complication of septicemia.

They had made blood cultures in fifty cases having symptoms resembling clinically septicemia. Fifty-seven per cent. of these cultures were positive, the streptococcus being the prevailing organism, although the staphylococcus was occasionally found, or a bacillus of the colon type in terminal infections. Of twenty-three patients with a positive blood culture, 74 per cent. died and 26 per cent. recovered. Of seventeen patients with a negative blood culture, 35 per cent. died and 65 per cent. recovered, showing that the percentage lacked only nine of being reversible. This showed the value of blood culture in suspected septicemia cases, not only in the diagnotic, but also in the prognostic sense. In the positive cases they had also the means for preparing an autogenous vaccine to assist nature. The total white count varied from 7100 to 25,000 in the patients who recovered; from 7000 to 30,000 in those who died. Ordinarily in this series of cases a low white count indicated a bad prognosis. However, a low white count might be found in patients with a severe type of septicemia and still recovery might quickly follow. The differential white count, on the other hand, was of the greatest importance. When the polymorphonuclear count approaches 90 per cent., particularly when the total white count was low, the prognosis became grave. They looked upon such a relationship as due to overstimulation of the mechanism of immunity. In only two of the patients who recovered was the polymorphonuclear count above 85 per cent.; in both of these, owing to the long continued infection, a severe grade of secondary anemia had developed. The blood picture was important because we were enabled thereby to determine the presence or absence of a severe grade of anemia or of acute leucemia. In most of these cases the antistreptococcic serums obtainable on the market had been employed before the writer saw the cases; in none was a cure reported. In several instances a marked drop in the temperature followed the use of the serum, but this was only a temporary response. In thirteen of the cases autogenous vaccines were employed in addition to the regular symptomatic treatment, and of this number seven recovered. This series of cases included seven cases of streptococcic septicemia, twelve cases of puerperal sepsis, six cases of purpura hemorrhagica and twelve atypical cases, all due to trivial wounds, surgical procedures, or localized septic processes, and three cases of septicemia following abdominal operations. In true septicemia the prognosis depended upon the state of health of the individual, the length of time the infection had existed, the type of organism causing the infection and the complications which might develop. The longer the course of the disease the more favorable was the prognosis. A negative blood culture and a polymorphonuclear count below 85 per cent. spoke for a favorable outcome. The patient should be treated as a consumptive, at least he should be given plenty of fresh air. He should be fed as generously as possible without deranging the digestion. The hot pack was indicated in septicemia marked by high temperature and erythema and in the absence of the more serious complications with stimulation before or after the pack. We might employ digitalis in the beginning to enforce the heart's action, though we could not thereby prevent the onset of endocarditis. Of the antipyretics quinine was the most important; it should be used in small doses and often. Bacteriocidal medication had been, on the whole, practically useless. Apparently good results had been obtained by hypodermoclysis. Antistreptococcic serum had little antitoxic and bacteriocidal value. Their experience had been limited to the use of autogenous vaccines and they believed their continued use was justified. The indications for surgical intervention when a pyemic abscess had developed were well known. Spinal puncture was indicated when symptoms of meningismus developed. The patient should be carefully watched during convalescence.

Treatment of Tuberculosis Pulmonalis by Tuberculin. Dr. A. N. SINCLAIR of Honolulu, Hawaii, presented this communication. He related his experience with tuberculin in the Leahi Home for Consumptives which had convinced him of the value of this agent. Out of 309 cases treated without the use of tuberculin in the four years prior to the adoption of the tuberculin treatment 27.2 per cent. of all cases treated were either arrested or were able to return to their former occupations, while out of 506 cases treated during the next four years with tuberculin 50.1 per cent. were enabled to resume their former occupation.

He had also found with reference to the efficacy of the tuberculin that there was an almost constant rise and fall of the average weight line parallel to the state of freshness of the diluted tuberculin. He had used this weight line to check up the potency of the tuberculin injected from week to week. In discussing the reasons for the failure of many others to get satisfactory results with tuberculin, he stated that he believed this was entirely due to lack of attention to details, to the omission or commission of some vital factor that appeared of minor importance. The essayist stated that he never had occasion to go above 1/300 mg. and rarely over 1/500 mg., instead of doses 1000 times as large (2 mg.). Next to the opsonic index the best control for the dosage was that first suggested by Sutherland; although, without desiring to detract from him the honor of this discovery, the writer had used a similar control at the Leahi Home for a number of years before this was published. This control was what might be termed the temperature reaction after injection. The main points to bear in mind were the day after the injection on which the highest temperature was reached, and whether or not normal was reached by crisis within twenty-four hours or by lysis. There were seven reactions which he recognized and in accordance with which he regulated the dosage. If the reaction was highest after 72 hours and there was no fall to normal after 72 hours tuberculin should be discontinued. A delayed reaction or continued high temperature indicated an inability to absorb the tuberculin and the dose must be decreased or halved, if continued. He usually began with 1/3000 mg. given weekly and increased by 1/3000. Another factor which he had taken into consideration was the amount of albumin in the sputum. A high albumin content, or one increased since the last dose of tuberculin, threw the decision towards decreasing or discontinuing the tuberculin; a low albumin content, or a decreased one, gave confidence in either repeating or increasing the dose. Tuberculin should never be given haphazard or by rule of thumb, experience alone enabled one to gauge the amount that should be given.

The Value of Tuberculin in the Treatment of Tuberculous Lymphnoditis.—Dr. GEORGE P. SANBORN of Boston presented this paper. He stated that this report was based on a series of sixty selected cases of lymphnodular tuberculosis treated in the Department of Vaccine and Serum Therapy of the Boston City Hospital, and a few of them in private practice. This group of cases included such as had developed under good conditions of hygiene and in which surgery was not primarily indicated and they therefore furnished fairly ideal experimental conditions. The feeding, housing, and general condition of these patients made possible the use of tuberculin as the one method of treatment without injustice to the patient. All cases received inoculations of bacillus emulsion, the initial dose in children being 1/50,000 to 1/25,000 mg.; in adults, 1/20,000 to 1/10,000. Both human and bovine tuberculin were used. The initial dose was sufficiently small to produce no subjective symptoms. The inoculations were given immediately beneath the skin so that the intensity of the reaction could easily be observed. Where the local reaction was considered suitable, dosage was usually held the same until its intensity became less. Dosage was then increased. Calcified and caseated glands could not be reduced by tuberculin and had been referred to the surgeon after a course of tuberculin had been given. Long continued tuberculin treatment might render the surgical problem of extirpation difficult. The results of tuberculin treatment in this series of cases might be summarized by stating that there was diminution in the size of the nodes in 83 per cent. of the cases; one or more nodes broke down in 33 1/3 per cent.; one or more lymph nodes developed during treatment in 20 per cent. of the cases; surgical procedures were necessary in 11 per cent.; there was a gain in weight in 60 per cent. In the possibilities of being favorably influenced by tuberculin, patients under fifteen years of age appeared to have the advantage. A demonstrable improvement had been observed in at least 83 1/3 of the cases treated. Recurrence took place in eight cases in this series.

Clinical and Pathological Observations on the Dangers Encountered in Certain Technical Procedures Frequently Used by Serologists and Clinicians.—Dr. H. S. MART-

LAND of Newark presented this paper, which gave a résumé of the contraindications, dangers and accidents met with in lumbar puncture, intraspinous and intracranial injections, intravenous medications, blood transfusions, etc. The observations of the author were based on clinical and pathological data, from over 1,500 autopsies at the Newark City Hospital. The paper included the presentation of pathological specimens.

Intravenous Therapy; The Use of Sensitized Bacterins Intravenously, Especially in Pneumonia.—Drs. WILLIAM EGBERT ROBERTSON of Philadelphia, Pa., and CLAUDE P. BROWN and ALLEN G. BECKLEY of Glendolen, Pa., presented this communication, which was read by Dr. Robertson. He stated that up to the present time bacterins had been given therapeutically most frequently in chronic, localized infections, less often in general infections. Treatment had usually been with the non-sensitized type and the mode of administration had been subcutaneous. Very little clinical use had been made of the intravenous administration of sensitized bacterins. Because sensitized bacterins, from a theoretical standpoint, would seem to give a quicker response in the production of immune bodies, and because with the intravenous mode of administration an immediate action of the bacterin might be secured with no attendant local reaction, the authors had employed serobacterins intravenously in a series of cases. One case of typhoid, treated in this way, gave very severe reactions after injections of the bacterin. Satisfactory recovery was made. Severity of reaction after the intravenous use of sensitized bacterins was typical in typhoid cases in general and was much more pronounced than in pneumonia treated in the same manner. In eleven cases of pneumonia two procedures were followed, some patients being given a polyvalent bacterin composed of sensitized pneumococci alone, others a mixture of sensitized pneumococci, streptococci, and staphylococci. Those receiving the pneumococci alone experienced no sharp reaction, while those receiving the mixed bacterin reacted with chill and subsequent rise in temperature accompanied by a marked change in the total white count and polynuclear increase. Of the eleven cases treated ten made a prompt recovery. The eleventh case, which terminated fatally, was complicated with nephritis. In the cases treated no detailed attempt was made to study the type of the infecting organism, but of seven cases in which this was done, three were of type I, three of type II, and one of type III. In preparing the pneumococcus bacterins, seven strains, including the three fixed types, were used. These were sensitized with the serum of goats and sheep, immunized against the various types.

Officers Elected for the Ensuing Year. — President, Dr. Richard Weil, New York City; vice-president, Dr. John A. Kolmer, M. D., Philadelphia, Pa.; treasurer, Dr. Willard J. Stone, M. D., Toledo, O.; secretary, Dr. Martin J. Synnott, M. D., 30 So. Fullerton Avenue, Montclair, N. J.; council, Dr. Arthur F. Cock and William H. Park, New York City.

STATE BOARD EXAMINATION QUESTIONS.

KENTUCKY STATE MEDICAL BOARD.

June 13, 14, 15, 1916

ANATOMY

1. (*a*) Describe the spinal cord, and (*b*) give its length, weight, points of beginning and ending in the spinal canal.
2. How many pairs of nerves are given off from the spinal cord?
3. (*a*) Locate and describe Peyer's glands, and (*b*) state where they are largest and most numerous.
4. What blood-vessels carry blood from the heart to and from the lungs?
5. Give the origin and distribution of the great sciatic nerve.
6. Describe the lymphatics of the liver.
7. Locate and describe the small intestine; state where it begins, where it terminates, and name the divisions.
8. Describe the esophagus, its structure, length, place of beginning and termination.
9. Name, locate and describe the bones of the arm and forearm.
10. (*a*) What bones form the pelvis, and (*b*) state the difference between the false and true pelvis.

PHYSIOLOGY.

1. Describe the medulla oblongata and discuss its functions.
2. Describe the digestion and assimilation of proteins.
3. Tell what you know of (*a*) the manufacture, (*b*) functions and (*c*) final disposition of white blood corpuscles.
4. Give in detail the functions of the kidneys.
5. Give the structure and functions of bone marrow.
6. (*a*) Discuss the essentials in the ventilation of a school room, (*b*) a bed room, and (*c*) the dangers of, and (*d*) tests for impure air.
7. (*a*) Differentiate between striated and non-striated muscles. (*b*) Give examples.
8. (*a*) Describe the sympathetic nervous system. (*b*) Give its functions.
9. (*a*) Describe the development of the humerus. (*b*) Of the temporal bone.
10. (*a*) Describe the most important vestibule of the body, and (*b*) give its functions.

BACTERIOLOGY.

1. (*a*) Describe in detail the method of immunizing a person against typhoid fever. (*b*) What is the dose for a child weighing 50 pounds?
2. (*a*) Describe the Widal reaction. (*b*) Give its value as a diagnostic symptom in typhoid fever.
3. (*a*) Describe the diphtheria organism; (*b*) its staining characteristics. (*c*) Give method of detecting diphtheria carriers.
4. Describe the organism of syphilis.
5. (*a*) Describe method of securing specimen for examination for malaria. (*b*) Differentiate the three varieties of the malarial organism.
6. Differentiate the ova of (*a*) *Ascaris lumbricoides*, (*b*) hookworm, (*c*) *Oxyuris vermicularis*.
7. How would you identify gonococci?
8. Give method of staining sputum for tubercle bacilli.
9. Describe the tetanus bacillus.
10. Describe the meningococcus.

ANSWERS.

ANATOMY.

1. "The *spinal cord* is the elongated portion of the cerebrospinal axis contained in the spinal canal. Its length is about sixteen to eighteen inches, extending from the medulla above to the lower border of the first lumbar vertebra below, where it terminates in the cauda equina by a slender prolongation of gray substance, called the conus medullaris. It presents two enlargements, the upper or cervical, extending from the third cervical to the second dorsal vertebra, and the lower about the position of the second or third dorsal vertebra. It is divided into two lateral halves by the anterior and posterior median fissures, united in the center by the commissure. The lateral portions are again subdivided by the antero-lateral and postero-lateral fissures into the anterior lateral and posterior lateral columns, and posteriorly a narrow fissure separates the posterior median column from the posterior median fissure. The gray substance occupies the center of the cord, and is arranged into two crescentic masses connected together by the gray commissure. The posterior horn forms the apex cornu, from which arises the posterior root of the spinal nerves. The anterior horn is thick and short, and affords origin to the anterior root of the nerves. The gray commissure contains throughout its whole length a minute canal the central canal, or ventricle of the cord, continuous above with the fourth ventricle." (Young's *Handbook of Anatomy*.) The spinal cord weighs about one and a half ounces.
2. Thirty-one pairs of spinal nerves are given off from the spinal cord.
3. *Peyer's patches* are aggregations of solitary glands, measuring from about half an inch to three inches in length; they are found mainly in the ileum, but also occur in the duodenum, and jejunum; they are situated lengthwise in the intestine, and are located opposite to the mesenteric attachment. Each patch is surrounded by a group of the crypts of Lieberkühn. There are said to be from 30 to 50 of these patches in the human intestine. As a rule, they have no villi on their surface.
4. The *pulmonary artery* conveys the venous blood to the lungs. The *pulmonary veins* convey oxygenated blood to the heart. The *bronchial arteries* supply blood for the nutrition of the lungs.

5. *The great sciatic nerve* arises from the sacral plexus, and passes out of the pelvis through the great sacrosciatic foramen, below the pyriformis muscle; it extends down the back of the thigh, passing between the great trochanter of the femur and the tuberosity of the ischium; at the lower third of the thigh it divides into the internal and external popliteal nerves. It supplies the hip-joint and the biceps, semitendinosus, semimembranosus, and adductor magnus *muscles*.

6. "*The lymphatics of the liver* are numerous, and consist of a superficial and a deep set. The former pass in various directions. Thus a large number go to the hepatic glands in the lesser omentum; others pierce the diaphragm and finally end in the right lymphatic duct; others (a few) go to the lumbar glands. As regards the deep set, some following the hepatic veins and inferior vena cava, end in the thoracic duct; others, following the portal veins, end in the hepatic glands. The efferents from the hepatic glands in the lesser omentum accompany the hepatic artery, and end in the celiac glands." (McLachlan and Skirving's *Applied Anatomy.*)

7. The *small intestine* is situated in the abdominal cavity. It begins at the pyloric end of the stomach, in the epigastric region and ends at the ileocecal valve in the lower part of the right lumbar region. Its average length is about 23 to 25 feet. It is divided into three portions, the duodenum, the jejunum, and the ileum. The duodenum is the first part of the small intestine, it is about ten inches long, and extends from the pylorus to the left side of the body of the second lumbar vertebra. The jejunum and ileum form the coils of the small intestine and are covered by the great omentum; they form the remainder of the small intestine, the upper two-fifths being the jejunum and the lower three-fifths the ileum; there is no line of demarcation between these two parts. The coils of the jejunum and ileum are suspended from the posterior abdominal wall by the mesentery. The wall of the small intestine is composed of four coats, a serous, muscular, submucous, and mucous.

8. The *esophagus* is a muscular canal, about nine or ten inches long, and extending from the lower border of the pharynx (at the upper border of the cricoid cartilage) to the stomach. It passes down along the front of the spine, through the superior and posterior mediastina, through the esophageal opening in the diaphragm, and ends in the cardiac orifice of the stomach (opposite the tenth dorsal vertebra). It is generally in the median line, but it curves to the left at the root of the neck and again at the esophageal opening in the diaphragm. It is composed of a general fibrous covering on the outside, then a muscular coat consisting of two layers, an outer longitudinal layer and an inner circular layer; inside this is a submucous coat of areolar tissue; and the esophagus is lined by a mucous coat which is covered by stratified squamous epithelium.

9. "The HUMERUS, or arm-bone, the largest and longest bone of the upper extremity, consists of a shaft, head, neck, greater and lesser tuberosities, and lower extremity.

"The *shaft*, cylindrical above, flattened and prismoid below, becomes twisted in the middle, and presents: A rough triangular surface about the middle of its outer surface for insertion of the deltoid muscle, and a musculo-spiral groove for the musculo-spiral nerve and superior profunda artery, on each side of which arise the external and internal heads of the triceps muscle.

"The *upper extremity* presents—the head, forming nearly a sphere, projecting upward, backward, and inward, articulating with the glenoid cavity; the anatomical neck, immediately beneath, is slightly grooved for the attachment of the capsular ligament; greater tuberosity, external to the head and lesser tuberosity, with three facets from before backward for attachment of supraspinatus, infraspinatus, and teres minor muscles; lesser tuberosity, smaller but more prominent than greater, is anterior to head, for the subscapular muscle; bicipital groove, passes downward and inward between the two tuberosities and lodges the long tendon of biceps; the anterior bicipital ridge, bounds the groove in front and receives insertion of pectoralis major muscle; the posterior bicipital ridge receives the latissimus dorsi and teres major; the surgical neck, including the head, neck, and both tuberosities; a rough impression near the center of the inner border for the coraco-brachialis muscle; nutrient canal, below and directed toward the lower extremity.

"The *lower extremity* presents from within outward the following: Internal condyloid ridge, extending upward from the condyle; internal condyle, more prominent than external, gives origin to the flexors and pronator radii teres; epitrochlea, an eminence separating the trochlea from the internal condyle; trochlea, a pulley-like articulating surface for greater sigmoid cavity of ulna; coronoid fossa, a small depression bounding the trochlea in front, and receiving the coronoid of the ulna in flexion; olecranon fossa, a larger depresssion behind, and receiving the olecranon process of ulna in extension; supra-trochlear foramen, sometimes formed by perforation of one fossa into the other; radial head, or capitellum, a smooth, rounded eminence articulating with cup-like depression on head of radius; external condyle, less prominent, gives origin to the extensors and supinators; external condyloid ridge, extending upward on the shaft from the condyle.

"It *articulates* with three bones—scapula, radius, and ulna. (Young's *Handbook of Anatomy.*)

"The RADIUS is a long bone, shorter than the ulna, situated on the outer side of the forearm, the upper end small, the shaft slightly curved, and the lower end expanded to form part of the wrist joint. It consist of shaft, upper and lower extremity. The *shaft* is prismoid, slightly curved, and presents: An *internal border*, sharp and prominent, for interosseous membrane; an *anterior border*, marked at its upper third by an *oblique line*, for attachment of flexor longus pollicis, supinator brevis, and flexor sublimis digitorum; *anterior surface*, affords attachment above for flexor longus pollicis, below for pronator quadratus, and presents at the junction of middle and upper two-thirds a *nutrient foramen* directed upward; *posterior surface* gives attachment at upper third to supinator brevis, and at middle third to extensors of thumb.

"The *upper extremity* presents: *Head*—a cup-like cylindrical cavity, for articulation with capitellum of humerus, and on its side an articulating surface for lesser sigmoid cavity of ulna and orbicular ligament, which nearly surrounds it; *neck*, the constricted portion below the head; *bicipital tuberosity*, below and to inner side, divided by a vertical line into a rough surface posteriorly, for attachment of biceps tendon, and smooth surface anteriorly for bursa.

"The *lower extremity*, large, expanded, and quadrilateral, presents: *Carpal articular surface*, smooth, concave, triangular depression divided by an antero-posterior ridge into an outer facet for scaphoid bone and inner for semilunar; *sigmoid cavity*, a shallow concavity at inner side of carpal end, for articulation with ulnar head; *styloid process*, projects obliquely downward from the external surface, for attachment by its apex to external lateral ligament of wrist-joint, and by its base to insertion of supinator longus muscle. Its outer surface is marked by two *grooves* for extensors of thumb. The *posterior surface* of the lower extremity is also marked by three *grooves* from without inward for the following: Ext. carpi radialis longior and brevior in first, ext. secundi internodii in second, and ext. indicis, ext. communis digitorum, and ext. minimi digiti in third. This surface has also attachment of posterior ligament of wrist."—(Young's *Anatomy.*)

"The ULNA is a long bone to the inner side of the forearm, and consists of a shaft and an upper and lower extremity. It forms the greater part of the articulation with the humerus, but does not enter into the formation of the wrist-joint, being excluded by the interarticular fibro-cartilage.

"The *shaft* is prismatic above, smooth and rounded below, and presents: *Anterior surface*, gives attachment to the deep flexors and pronator quadratus; *nutrient foramen* on anterior surface, directed upward toward the elbow-joint; *posterior surface* marked above by an *oblique line* for part of supinator brevis, above which is smooth triangular surface for anconeus muscle, and the lower third for extensor muscles of the thumb; *external border*, sharp in middle two-thirds, for attachment of interosseous membrane.

"The *upper extremity* is large and irregular, and presents: *Olecranon process* (head of elbow), projects upward and forward, its apex being received into the olecranon fossa of the humerus in extension of the forearm; its upper border has rough impression for the triceps muscle; its lateral borders are grooved for external and internal lateral ligaments; coronoid process, smaller than olecranon, projects forward from anterior surface, being received into coronoid fossa of humerus in flexion. Its *supper surface* forms part of the great sigmoid cavity. Its *under surface* has rough impression for insertion of brachialis anticus, and has, at its junction with the shaft, the *tubercle of the ulna* for the oblique ligament. Its *outer surface* is the lesser

sigmoid cavity. Its *inner surface* gives attachment to the internal lateral ligament, and the flexor digitorum sublimis, flexor profundus digitorum, and one head of pronator radii teres. *Greater sigmoid cavity* is a large, semi-lunar depression between the olecranon and coronoid processes, divided into two unequal lateral parts by an elevated ridge. It is continuous on the outer side with the lesser sigmoid cavity and articulates with the trochlear surface of the humerus. *Lesser sigmoid cavity* is an oval, concave, articular depression, external to the coronoid process, for articulation with the head of the radius. Its prominent extremities give attachment to the orbicular ligament.

"The *lower extremity* is small and cylindrical and presents: *Head*, an external, rounded, articular process, for the triangular fibro-cartilage below and the sigmoid cavity of the radius externally; *Styloid process*, projects from the posterior and internal part of the extremity, its apex gives attachment to the internal lateral ligament of the wrist, and it is marked at its root by a depression between it and the head, for attachment of the fibro-cartilage; *groove*, upon the posterior surface, for passage of extensor carpi ulnaris It articulates with two bones—humerus and radius." (Young's *Anatomy*.)

10. The *pelvis* is formed by the two ossa innominata, the sacrum and the coccyx; each os innominatum is made up of ilium, ischium, and pubis.

The *false pelvis* is that expanded portion of the pelvis above the iliopectinal line and the upper margin of the symphysis pubis. The *true* pelvis is the part beneath this plane. It is smaller, and has more perfect walls than the false pelvis.

PHYSIOLOGY

1. The *medulla oblongata* is the lowest part of the encephalon, and is continuous below with the spinal cord. It extends from the lower margin of the pons to the lower margin of the foramen magnum. It lies in the basilar groove of the occipital bone; its dorsal surface is between the cerebellar hemispheres. It forms the lower part of the floor of the fourth ventricle. It is about one inch long, half inch wide, and half inch thick. It has anterior and posterior median fissures, which are continuous with those of the spinal cord.

The *functions of the medulla oblongata* are: (1) It is a conductor of nervous impulses or impressions from the cord to the cerebrum, from the brain to the spinal cord, also of co-ordinating impulses from the cerebellum to the cord; (2) it contains collections of gray matter which serve as special nerve centers for the following functions or actions; respiration, salivary secretion, mastication, sucking, deglutition, speech production, facial expression; it also contains the cardiac and vasomotor centers.

2. *Proteids* are digested in the stomach (by the pepsin of the gastric juice) and in the small intestine (by the trypsin of the pancreatic juice).

During digestion the proteids are split up into proteoses, peptones, polypeptides and amino-acids. The amino-acids are believed to be taken as such by the epithelial cells and carried to the blood of the portal capillaries. Another view is that in the intestinal epithelium the amino-acids are built-up again into proteins such as are found in the blood. There are three theories of the further history of the proteids. According to one of them (the theory of Voit), "the protein of the tissues, living or organized protein, is to be differentiated from the absorbed circulating protein. It is only in this circulating protein, which is assumed to be present in the fluids of the body, the blood and lymph, that catabolic changes take place. These changes take place under the influence of the living cells. The more resistant organized protein is not supposed to undergo catabolic changes. If any of it does, it is cast off into the fluids of the body, and thus becomes circulating protein, undergoing catabolic changes in precisely the same manner. It is obvious that a small part of the absorbed protein must be utilized to replace the waste of the organized protein and to subserve the process of growth. This portion is termed tissue protein." (Lyle's *Physiology*.)

3. *White blood corpuscles* are *formed* in the spleen, lymph glands, and lymphoid tissue; also from other white cells by direct cell-division in the blood stream; the eosinophiles may be derived from the bone marrow. Their *fate* is uncertain: it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells. Their *functions* are (1) to serve as a protection to the body from the incursions of pathogenic microrganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

4. The *functions of the kidney* are: (1) To secrete (or excrete) urine; (2) to regulate the reaction of the urine; (3) the formation of hippuric acid; (4) regulation of the composition of the blood plasma by excretion of abnormal or toxic substances; and (5) the production of an internal secretion. The mechanism of the *secretion of urine by the kidneys* is twofold: (1) By filtration, most, if not all, of the fluid is eliminated, and also inorganic salts; this depends upon blood pressure, and takes place in the glomeruli. (2) By cell activity and selection, in the cells of the convoluted tubules, the urea, and principal solids are eliminated.

5. BONE MARROW. "*Red marrow* is the connective tissue which occupies the spaces in the cancellous tissue; it is highly vascular, and thus maintains the nutrition of the spongy bone, the interstices of which it fills. It contains a few fat-cells and a large number of marrow-cells. The marrow cells are ameboid, and resemble large leucocytes; the granules of some of these cells stain readily with acid and neutral dyes, but a considerable number have coarse granules which stain readily with basic dyes like methylene blue. Among the cells are some smaller nucleated cells of the same tint as colored blood corpuscles. These are termed erythroblasts. From them the colored corpuscles of the blood are developed. There are also a few large cells with many nuclei, termed giant cells or myeloplaxes. *Yellow* marrow fills the medullary cavity of long bones and consists chiefly of fat-cells with numerous blood-vessels; many of its cells also are the colorless marrow-cells just mentioned." (Halliburton's *Physiology*.)

6. (*a*) *The essentials in the ventilation of a schoolroom* are that there must be 1,000 cubic feet of space for each individual, that the air in this space must be changed three times in an hour, that the air must be warmed to 60° to 65° Fahr., and that it must be moistened and purified (or at least strained to remove excessive dust. "There is considerable difference of opinion as to the best locations for inlets and outlets, and as the conditions are necessarily different in every case and so many factors are to be considered, it is difficult to lay down any general rules. It should be an aim, however, to have the air well distributed and to have no direct draughts from the inlets either upon the occupants or to the outlets. Usually the outlets should be located near the top of the room, owing to the tendency of the used air to rise, and because, in unventilated rooms, the foulest air for some time after its contamination will be found nearest the ceiling. The products of combustion from lights, etc., will also practically all be in the upper strata of air. If, however, provision is or can be made for a constant and sufficiently strong aspirating force in the outlet ducts, it may be advisable to withdraw the used air from near the floor level and below the inlet openings, though not in too close proximity to them, since in this way a more thorough distribution of the incoming air and a greater dispersion of its contained heat are secured. The location of the inlets should depend on the temperature of the incoming air; if it is cold it should be admitted near the ceiling, so that it may diffuse and be partially warmed before reaching the inmates of the room; if it is warmed it may come in near the floor or below the middle level of the room." (Egbert's *Hygiene and Sanitation*.)

(*b*) In a *bedroom*, for adults, proper ventilation may be secured by having double windows, or double panes of glass, with an opening at the bottom of the outer and at the top of the inner one, so that the fresh air may enter in an upward current; or by placing a board under the lower sash so that fresh air can enter in the middle.

(*c*) The *dangers of impure air* are: Drowsiness, headache, digestive disturbances, mental dullness, and disease or liability to take disease. The chief danger to health is in the increase of carbon dioxide, the presence of crowd-poison, dust, irrespirable gases, and bacteria.

(*d*) The relative amount of carbon dioxide in the air is taken as an indication of its purity; not because the carbon dioxide is itself harmful in the amounts generally encountered, but because it is readily estimated and is a fair indicator of the purity of the air.

Pettenkofer's method of determining the percentage of carbon dioxide in the air: A large cylindrical con-

tainer of known capacity, say, 15 liters, is filled with the air to be examined; a known volume of barium hydroxide is then added and shaken up with the air. The carbon dioxide combines with the barium hydroxide to form a barium carbonate, which is insoluble, and also incapable of acting upon an indicator. The barium hydroxide employed is of known strength, *e.g.*, it may be of such strength that 1 c.c. of the solution neutralizes 1 c.c. of carbon dioxide at normal temperature and pressure. If then we find that 10 c.c. of the barium hydroxide has been neutralized by the carbon dioxide present in the air, we know that 10 c.c. of carbon dioxide is present in 15 liters or 15,000 c.c. of the air examined.

7. *Voluntary muscle* is more or less under the control of the will, does not contract rhythmically, does not evince peristalsis; *involuntary* muscle is not under the control of the will, it is rhythmical in its contractions, and is also characterized by peristalsis.

Further, *voluntary* muscle is striated, has long narrow fibers with cross striations and many nuclei beneath the sarcolemma. *Involuntary* muscle is nonstriated, has spindle-shaped fibers, one nucleus centrally located, and no sarcolemma. The great exception is cardiac muscle, which is involuntary and also striated. *Voluntary muscle* is found in all the skeletal muscles, pharynx, diaphragm, larynx, external ear, and eye. *Involuntary muscle* is found in the alimentary tract from the middle third of the esophagus to the anus, in the ducts of glands, in the trachea and bronchial tubes, within the eyeball, the internal urinary and genital systems, circulatory (except the heart) and lymphatic systems, and the capsules of some organs.

8. "*The sympathetic nervous system consists of* (1) a series of ganglia connected together by a great ganglionic cord, the gangliated cord, extending from the base of the skull to the coccyx, one gangliated cord on each side of the middle line of the body, partly in front and partly on each side of the vertebral column; (2) of three great gangliated plexuses or aggregations of nerves and ganglia, situated in front of the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of smaller or terminal ganglia, situated in relation with the abdominal viscera; and (4) of numerous fibers."—(Gray's *Anatomy.*)

Function: It has a controlling influence over the secretion of most of the glands, the lacrimal, the salivary, the sweat glands, the glands of the stomach and intestines, the liver, the kidney, etc.; it presides over the circulation by regulating the caliber of the blood-vessels and the action of the heart; it influences respiration; and, all involuntary muscles, those of the digestive apparatus, of the genitourinary system, of the hair follicles (pilomotor nerves), are under its control to a great extent.

9. *Development of the humerus.* "Ossification occurs from a primary center in the shaft and six or seven secondary centers in the extremities. In the upper extremity centers appear in the head, great tuberosity, and sometimes in the small tuberosity, which, after fusing together, join the shaft about the twentieth year. In the lower extremity centers appear in the trochlea, capitellum, and outer and inner condyles, the three former of which, after coalescing, unite with the shaft in the seventeenth year. The inner condyle forms a distinct epiphysis which unites somewhat later." (Gerrish's *Anatomy.*)

Development of the temporal bone. "The squamosal and tympanic bones ossify in membrane, each from a single center; the petrous portion and styloid process in cartilage, the former from four centers, the latter from two. The fetal tympanic bone forms an incomplete ring, which incloses the tympanic membrane. It is open above with its free ends united to the squamosal. The defect in the ring due to this opening above is known as the notch of Rivinus. Two tubercles, one growing from the front and the other from the back of this ring, meet in the floor of the meatus, enclosing a foramen, which is gradually (though not always) closed, and thus the tympanic plate is formed. At birth the mastoid process, articular eminence, and tympanic ring are flat, the glenoid fossa is shallow, and the hiatus Fallopii opens at the genu of the canal." (Gerrish's *Anatomy.*)

10. *The vestibule of the internal ear.* "The vestibule is situated on the inner side of the tympanum, behind the cochlea and in front of the semi-circular canals. It is somewhat ovoid in shape, and measures about one-fifth of an inch in length. On its outer wall is the fenestra ovalis, closed by the base of the stapes and membrane; on its inner wall is the fovea hemispherica, pierced by minute holes, for the filaments of the auditory nerve and opening of the aqueductus vestibuli; on its roof is a small depression, the fovea semi-elliptica; behind are the five openings of the semi-circular canal, and in front an opening which communicates with the cochlea." (Ashby's *Notes on Physiology.*) The *function of the vestibule*—It is supposed to be concerned with equilibrium.

BACTERIOLOGY.

1. *Method of immunizing against typhoid.* The vaccine is administered subcutaneously over the insertion of the deltoid muscle; the site of the injection should have been previously painted with tincture of iodine; intramuscular injections are to be avoided; after the injection has been given the iodine is wiped off with a pledget of cotton and alcohol; no dressing is needed; the syringe and needle must be sterile; three such injections are given at intervals of about ten days; the dosage for adults (of 150 pounds weight) is 500 million bacilli for the first injection, and 1000 million bacilli for the second and third injections; each of these amounts is contained in about fifteen minims or one cubic centimeter; for a child weighing fifty pounds the dosage should be about one-third of the above, or a little more, for children take the injections very well.

2. (*a*) The Widal test for typhoid fever "depends upon the fact that serum from the blood of one ill with typhoid fever, mixed with a recent culture, will cause the typhoid bacilli to lose their motility and gather in groups, the whole called 'clumping.' Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. . . . A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps, and cease their rapid movement inside of twenty minutes."—(From Thayer's *Pathology.*)

(*b*) Its diagnostic value is believed by some to be great; others place little reliance on it. It may be absent in cases of typhoid fever; it may be present for several months after an attack of typhoid; the reaction may not be obtained till the third week of the disease; it may be present in other diseases or in perfectly healthy persons. The above have all been urged as objections; certainly only positive results have any value at all.

3. The *characteristics of the bacillus of diphtheria:* The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are non-motile, and aërobic; they are noted for their pleomorphism; they do not stain uniformly, but stain with any aqueous solution of an anilin dye, they also stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue; Neisser's stain is also recognized.

Diphtheria carriers can only be detected by the finding of the diphtheria bacilli in the secretions of their nose and throat. A sterile swab is rubbed over any visible membrane on the tonsils or throat and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours, when it is ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it and placed on a clean cover slip and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli of diphtheria appear as short, thick rods with rounded ends; irregular forms are characteristic of this bacillus, and the staining will appear pronounced in some parts of the bacilli and deficient in other parts. *Methods of culture:* The bacillus of diphtheria grows upon all the ordinary culture media, and can be readily

obtained in pure culture. Loeffler's blood serum, particularly with the addition of a little glucose, is an admirable medium for the rapid growth of this bacillus. The medium should be alkaline and not less than 20° C.

4. Syphilis is due to infection by the *Treponema pallidum*, also called the *Spirochæta pallida*. This is a slender spirillum, with regular turns, the curves varying in number from three or four to twelve or even twenty; it is about 4 to 20 mikrons long, actively motile, with a fine flagellum at each pole; it is flexible, hard to stain, and has not been cultivated on artificial media. How it divides is not known. It stains best with Giemsa's eosin solution and azur.

5. *In examining for malaria:* "Prepare some perfectly clean and very thin cover slips, and remove all traces of grease. Cleanse the skin of the finger-tip or ear with soap and water, and then with alcohol and ether. Make a *small prick* in the skin. Wipe away the first drop of blood, leaving a perfectly dry surface, so that subsequent drops will not run. Squeeze out a tiny drop about the size of a large pin's head. Touch the apex of this drop with the center of a cover glass, and immediately drop it, face downward, on a perfectly clean slide. Make several such preparations, and reject all those in which rouleaux are present. It is absolutely essential that the red corpuscles should lie flat. Examine with a 1/12 immersion lens and rather feeble illumination. Look in the red corpuscles for the presence of small black specks, often rod-like and showing slow movements of translation. These are surrounded by clear areas. One may also see in the center of some of the red cells clear ameboid areas which show no pigment. Rosette forms may also be visible. These forms of the parasite are always present in cases of malaria which have not had quinine. Other varieties are only met with in some chronic cases. Of these there are two chief forms: (1) The crescentic, (2) the flagellated. These are easily recognized. The crescentic bodies are highly refractile, rather longer than a red blood corpuscle, and about 2μ in diameter. Particles of pigment may be recognized in the parasite and also in some of the ordinary leucocytes."—(Hutchinson and Rainy.)

TERTIAN.	QUARTAN.	ESTIVO-AUTUMNAL.
Cycle in man 48 hours.	3 days.	24-48 hours.
Ameba in red cell active.	Sluggish.	Smaller than tertian.
Decolorizes red cell rapidly.	Slowly.	Hemoglobin deeper in tint.
Causes red cell to swell.	Size preserved or diminished.	Red cells shrivel.
Outlines not sharply defined.	Sharp.	
Pigment in fine granules, abundant, in motion.	Coarser, fewer.	Pigment in fine peripheral granules, not often in motion.
Spores 15-20, usually 18, small.	6-12, larger.	Small, 6-30, usually 18.
Flagella more numerous.		Less numerous.
Ring forms common, early, more distinct than those of estivo-autumnal.		Common, ring and disk form less distinct.

—(Thayer.)

6. The *ova* of *Ascaris lumbricoides* "are elliptical with a thick (4μ) transparent shell and an external albuminous coating which forms protuberances; the ova measure 50μ to 70μ in length, 40μ to 50μ in breadth; they are deposited before segmentation; the albuminous coating is stained yellow by the coloring matter of the feces, but it is sometimes absent. The egg cell is unsegmented, it almost completely fills the shell, and its nucleus is concealed by the large amount of coarse yolk granules."

The *ova* of *Ancylostoma duodenale* "appear to have a single contour. Under high powers this appears double, but they are the outer and inner surface of the true (chitinous) egg-shell. Internal to this is the extremely delicate yolk-envelope, a kind of skin secreted by the egg cell around itself for protection. The eggs are oval, with broadly rounded poles, 56μ to 61μ by 34μ to 38μ. In *fresh* feces they contain four granular nucleated segmentation masses of the ovum separated by a clear space from the shell."

The *ova* of *Oxyuris vermicularis* "are oval, asymmetrical, with double-contoured shells, and measure 50μ to 55μ by 16μ to 25μ; they are deposited with clear, non-granular tadpole-like embryos already developed." (From *The Animal Parasites of Man*, by Fantham, Stephens, and Theobald.)

7. *Gonococci* are recognized by their form (diplococci), their location (intracellular), and their staining properties (eosin and methylene blue, and being decolorized by Gram's method); they are exceedingly difficult to cultivate, and this feature renders differentiation from the *Micrococcus catarrhalis* easy, inasmuch as the latter grows readily on simple culture media.

8. To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods while all other bacteria will appear blue. The tubercle bacillus is rod shaped, is from 1½ to 3½ mikrons in length and about one-third to one-half a mikron in breadth, is a strict parasite, is not motile, and has no flagella. It is slightly curved, does not form spores, is not liquefying; is nonchromogenic; is aërobic; it resists acids; it grows well on blood serum; stains well by Ehrlich's, Ziehl-Neilsen's, or Gabbett's method; it is Gram-positive.

9. *The bacillus of tetanus* is characterized by its peculiar spore, formed at one end of the bacillus and giving it the appearance of a pin; it is purely anaërobic, and cannot be developed at all in the presence of oxygen. It generally comes from the soil, and is found in penetrating wounds. It appears in two forms, the spore-bearing form, as described above, and the vegetative form, which is a short bacillus with rounded ends, and which may occur singly or in pairs, or may form long filaments. It grows in gelatin stab cultures in the middle of the medium and the colonies look something like a fir tree; its growth is slow, and a disagreeable odor is at the same time emitted. In bouillon, it grows near the bottom of the tube, and produces gases.

10. The *meningococcus* is a small, non-motile, non-flagellate coccus; it does not form spores, does not liquefy gelatin, is aërobic, and pathogenic; it appears in diplococcus groups, and may be found within or outside the cells; it stains readily with the ordinary anilin dyes, but is Gram negative. It grows readily upon meat infusions, and especially so on media to which ascitic fluid or blood serum has been added.

(*To be continued.*)

Antirabic Service of the Pasteur Institute in Tunis for 1915.—The total number of cases treated was 443, from which number must be deducted twenty-three (fifteen cases in which dog was not shown to be rabid and eight who abandoned treatment). There were five deaths of patients under treatment, due to severity of infection or late arrival at the institute. The total number thus far treated at the latter is 5,711, with eighteen deaths. The animals had homes in about one-half the cases, the others being strays. The large number of pet animals is difficult to explain. In only forty cases was diagnosis made by inoculation. In sixty-two the veterinary diagnosis was made, and all other animals were merely suspects.—*Archives de l'Institut Pasteur de Tunis.*

Pellagra.—Jelks concludes an article on this subject as follows: "We never saw a pellagrin in this country until a few years ago, yet there are in the State of Mississippi alone perhaps 5,000 cases to-day, at least 3,500 of which have been reported this year. Many cases are not reported as pellagra at all. There are perhaps 50,000 cases of pellagra in this country to-day and the disease is increasing at an appalling rate. It is a fact that usually the skin symptoms, upon which so many rely for a diagnosis, are late symptoms, or may escape entirely the casual observer. Certainly we must learn to make diagnosis of pellagra or rather the condition upon which depends this misnomer, and late symptom.—*Pacific Medical Journal.*

HYDROLOGY IN MILITARY PRACTICE.*

BY GUY HINSDALE, A.M., M.D.,
HOT SPRINGS, VA.
FELLOW OF THE ROYAL SOCIETY OF MEDICINE.

"THE old order changeth," and nowhere will the change be more noteworthy than in the attitude of travelers and health-seekers toward European spas. American and English tourists will some day seek again the Continental watering-places, but it is safe to predict that a generation will pass before they flock to Teutonic resorts as in the past. We shall never hear of a British King visiting Homburg again, and it is doubtful if Americans will spend their millions annually in Karlsbad, Wiesbaden, and Nauheim for years to come. British watering-places will undoubtedly have a revival, and the innumerable French spas will surely gain immensely in popularity with all English-speaking travelers. This is but natural, and it does not require a prophet to foretell it.

In England a systematic effort has been made in the last year to afford wounded and invalid soldiers and sailors the benefits of spa treatment at home.

A committee of the Royal Society of Medicine has been charged by the War Office with this service, and has carefully examined its resources with this end in view. The peculiar adaptation of each one of the forty-five different resorts has been stated in a report recently issued, and consequently their doors have been opened to thousands of soldiers and sailors invalided home. No doubt the soldier who is sent to Buxton, Harrogate, or Bath will be more fortunate than his comrade who finds himself in the best of London hospitals unless he needs the special skill of some metropolitan consultant. Even the remedial uses of air and water may often overbalance the skill of the best specialist.

It is the intention to distribute cases wherever the best treatment can be afforded, and it is found that the spas and other bathing establishments in Great Britain afford special advantages for after-treatment.

The surgical affections which are amenable to treatment in this manner include contusions and bruises, sprains and strains of joints, fracture near joints with immobility, fractures imperfectly healed, unresolved effusions, fractures with osteitis and necrosis (obstinate cases), wounds unhealed and painful scars, cases where arterial circulation is locally deficient, as from the effects of pressure or frost-bite, and, finally, cases after operation.

Ills Spas May Heal.—Among the medical affections appropriate for spa treatment are rheumatic disorders, fatigue fever and muscular rheumatism, or subacute fibrositis, all of which are liable to follow fatigue and exposure; sciatica and lumbago, convalescence from rheumatic fever, chronic articular rheumatism, synovitis, and degenerative arthritis.

Among the circulatory disorders are defective peripheral circulation, cardiac dilatation, Graves's disease, and tachycardia.

Nervous diseases form a very important class, including the condition of nervous shock resulting from traumatism, mental shock or operation, neurasthenia and psychasthenia, irritative conditions with excitement and insomnia, and melancholia. Then, also, the palsies, both central and peripheral, the atrophies and the terrible cases of peripheral neuritis and kindred afflictions which Drs. Mitchell, Morehouse, and Keen cared for during our own great war. Then comes the long list of digestive, hepatic, respiratory and cutaneous disorders. The committee has indicated appropriate climatic and hydrologic treatment, and the particular places where these can be afforded.

I have recently received from Dr. Charles W. Buckley, of Buxton, an account of the treatment afforded soldiers at that famous spa. In his letter he says:

> It will perhaps be best if I first describe what is being done here. Buxton, with Bath and Harrogate, is doing very much the same in the matter, while the smaller spas, Droitwich, Woodhall Spa, Llandrindod, Strathpeffer, etc., are using their resources so far as they go.
>
> In Buxton the large mineral-water hospital known as the Devonshire Hospital, which has 316 beds and a complete installation of baths, has placed 200 beds at the disposal of the military and naval authorities for the treatment of rheumatic disorders and such other conditions as are likely to benefit by the Buxton climate and special forms of treatment. About 1,500 patients have been treated so far, with a very large proportion of cures. Very few cases of wounds are received, and only those in which massage or similar treatment is required for the treatment of stiffness, nerve injuries, etc. A fair proportion of cases of nerve shock are sent, but, except in the milder forms, would be better treated in institutions more especially devoted to that class of case. The great bulk of the cases are rheumatism, articular or fibrous (muscular), sciatica, gonorrheal and traumatic arthritis, and what is known as "Flanders foot," a form of frost-bite due to standing in trenches up to the knees or higher in cold water.
>
> There is also a Red Cross hospital of fifty beds; the cases are of similar type, but with a larger proportion of men sent to convalesce after wounds. They have their balneological treatment at the municipal bathing establishment. In both hospitals, while mineral-water treatment, baths, douches, etc., is the chief therapeutic measure, massage and electrotherapy, especially ionization, are employed.
>
> The Canadian Red Cross Society has just established a hospital of 300 beds in the town for the treatment of special cases similar to those dealt with at the hospitals already referred to, but it is expected that cases of nerve shock will receive special consideration at this hospital. It will have its own electrotherapeutic establishment, but will send cases for mineral-water treatment to the municipal establishment. It will be staffed by officers of the Canadian Army Medical Corps,

*Read at the thirty-third annual meeting of the American Climatological and Clinical Association at Washington, May 9, 1916.

but for the special treatment by the mineral water two local practitioners have been given honorary commissions in order that their special experience may be available. I have the honor to be one of these.

For officers requiring treatment special arrangements have been made for their accommodation at hotels, etc., in the town. They receive free treatment at the baths and free medical attendance.

Both at Harrogate and Bath the mineral-water hospitals have been largely or entirely given over to soldiers, but as they are both smaller than the Buxton hospital they do not accommodate so large a number of military cases, I believe. In Bath there is also a Red Cross hospital and a V. A. D. hospital; there is no essential difference, I think, between these two organizations; there is also a small hospital for officers. Primarily these hospitals are for cases likely to receive special benefit from the spa in question, but, as in the case of Buxton, wounded soldiers are received as well. A large hospital of 500 beds is about to be opened at Combe Park, near Bath, and staffed by the local doctors, but this will be for wounded soldiers and not for special bath treatment. At Harrogate the Grand Duchess George of Russia maintains a private hospital, and there are also hospitals under the V. A. D. system on the same lines as those already referred to. In the smaller spas the mineral-water hospitals are also in use for soldiers, supplemented by small V. A. D. hospitals.

We have no hydrological institutions in this country strictly comparable with those in the States. The so-called hydropathics are often no more than pensions or hotels with a small equipment of baths and simple forms of douche; a few of these have taken soldiers for special treatment, but I cannot give you any details beyond what you will find in the small book published by the Health Resorts Sub-Committee of the Royal Society of Medicine, which you already have.

Yours sincerely,

CHARLES W. BUCKLEY.

France is sending her wounded as far as Biarritz and Nice and the neighboring Riviera, and we hear that Vichy and Aix-les-Bains are full of soldiers "taking the cure" until able to join the ranks again, if need be. One of the great sources of reputation of Aix was the remarkably good results achieved in affections of the joints and in supplementing the work of the military surgeon. The soldiers of Napoleon went there, and recovered and fought again in later campaigns.

I have recently received from Dr. Margnat, of Vichy, who is now in command of a field ambulance, a letter in which he describes the efforts which the sanitary corps is making to afford balneologic treatment to the troops in the present war. The spas in France which are receiving sick and wounded soldiers by direction of the War Office are Amélie-les-Bains, Barèges, Bourbonne-les-Bains, Bourbon-l'Archambaut, Vichy, and Plombières. In Algeria they are utilizing Hammam R'hira, Bains de la Reine, and in Tunis, Hamman Lif. In cases where the springs belong to the Government, the soldiers sent for treatment are under the rules in force in military hospitals; but in other cases arrangements are made with the private owners for the use of the establishment as may be required.

Mineral spring hospitals receive, first, soldiers and sailors on active service; next, soldiers and sailors on non-active service, either invalided or retired, and, finally, officials in the Colonial, Customhouse, or the Forestry Service. Cases sent for treatment are subject to selection by Army surgeons, and are restricted to those in which ordinary means of treatment have been used during a sufficient length of time without success. They may therefore be considered chronic cases.

At Vichy the thermal military hospital, which is assigned to the soldiers' balneologic treatment, has about 300 beds. It is open from May 1 to September 15. This interval is divided into six seasons: (1) from May 1 to 21, (2) from May 24 to June 13, (3) from June 16 to July 6, (4) from July 9 to 29, (5) from August 1 to 21, and (6) from August 24 to September 13.

The military patients are distributed beforehand between these different seasons; they must all arrive on the same day and leave on the same day as well.

The interval of two days between each period is used for cleaning and disinfecting the hospital.

In the hospital itself there is a bathing establishment where the patients take their cure of baths and douches. Like the patients in civil life, they drink at the "buvettes" belonging to the Government.

The soldiers' cure is directed by military doctors specially appointed by the sanitary corps, but generally not belonging to the station.

With its 300 beds the military hospital in Vichy provides treatment for thousands of patients.

The other stations capable of receiving soldiers have less important organizations, and with the exception of Amélie, which has three, they do not all possess a special establishment for soldiers. Plombières, Bourbon l'Archambaut, Barèges use the civil establishments for treating the military patients.

The treatment at Vichy is indicated for digestive troubles, dyspepsia, rheumatic and gouty gastralgia, enteritis and chronic colitis, liver and spleen engorgements (especially after malaria, hepatic colics, uricæmia, uric lithiasis, gout, renal colics, arthritism, obesity, and diabetes).

Barèges and Amélie-les-Bains for old painful wounds, old fistulous wounds, retracted muscles, old joint diseases, local tuberculosis with no infection of the lungs, indolent ulcer, cutaneous herpetic trouble, inveterate syphilides.

Bourbonne-les-Bains and Bourbon-l'Archambaut for lymphatism and scrofula, chronic rheumatism, sciatica, muscular atrophy, traumatic arthritis, stiffness of the joints.

Plombières for visceral rheumatism, gastralgia, enteric dyspepsia, chronic dysentery, painful engorgement of the liver, painful cystitis, sciatica, neuralgia, traumatic neuralgias.

In the present war the spas have played a very important rôle, but at the same time a very complex one. They are serving a useful purpose for the wounded owing to their many hotels, and for their physiotherapeutic resources in the treatment of troubles consequent upon wounds. The thermal military hospitals afford the balneologic treatment proper to each station, so that now soldiers can follow balneological treatments not only in the abovementioned spas, but also at Neris, Aix, Salies-du-Béarn, le Mont-Dore, Uriage, Luchon, Châtelguyon, Cauterets, Dax, Argelès, etc.

Dr. Margnat says he has no statistics of the results obtained from balneological methods. But from a few particulars which have been procured, balneotherapy, with douche massage and hot baths, has given excellent results in a series of wounds and stiffness of the joints, especially in muscular troubles.

Hypertonic baths, such as those of Salies-du-Béarn, have been extremely favorable to wounds slow to heal, and Neris's hyperthermal baths to acute articular rheumatism.

Vichy, with its extensive bathing establishment (douches, massage, mineral baths, Zander institute), has contributed to the recovery of an incalculable number of wounded.

The rôle of the balneologic treatment of troops having taken part in the war will certainly not be over with the latter. We anticipate an organization after the war which will utilize all resources to remedy as much as possible the diseases and infirmities of warfare.

I am informed that at Karlsbad there are about 3,000 soldiers sick or wounded. Of the medical men usually in practice at that spa only two are reported to be left, and these are over 70 years of age. The use of the baths is probably, therefore, in the hands of attendants or military surgeons.

Dr. Heinrich Kisch, of Marienbad, is credited with having proposed fifty years ago that the Bohemian health resorts should be accorded neutrality in war time. He made this proposal when war between Austria and Prussia was threatened:

"It was considered at a parliamentary sitting in Prague, December 7, 1866, and the Government was asked to further the project. Count Forgach, then Governor, lent his aid. In August, 1867, there was an international conference in Paris on the aid societies for wounded soldiers. Dr. Kisch sent a pamphlet to all who took part to persuade them to use their influence in favor of the idea and to decide that a supplementary article should be added to the articles of the Geneva Convention. Surgeon-General von Langenbeck spoke in favor of Kisch's proposal in the Paris Conference, and requested that all health resorts should be regarded as neutral within the area of war.

"During the long period of peace nothing was done about it. In 1912, during the Balkan War, Dr. Kisch took the matter up again. The president of the Austro-Hungarian Association of Health Resorts addressed a memorandum to the Foreign Secretary of State and asked his support in this matter. Meanwhile, in August, 1914, the great European War broke out. The Foreign Ministry replied that the matter was being given serious consideration. The law of December 26, 1912, permits the utilization of health resorts for military purposes in case of necessity. According to the Geneva Convention of July 6, 1906, military hospitals are protected, as are also institutions in health resorts which are employed for the military health service. Against declaring health resorts in general as neutral, said a high official of the Ministry of War, there are circumstances which must be very thoroughly considered.

"Dr. Kisch is a man of perseverance, and has not given up hope of being able to realize his idea after the war. He thinks that this war has proved the important rôle played by the health resorts in curing wounded and sick soldiers, and that this fact will lead after the termination of the war to repeated negotiation of his proposal. He believes he will live to see his idea accepted. In this case he said to an interviewer that Goethe's words will prove to be true: 'Was man in der Jugend gewünscht, bietet das Alter in Fülle' (That which one has wished for in his youth, age offers in fullness)."—*Journ. Amer. Med. Assn.*, April 29, 1916.

Bath Trains.—It is interesting to note that bath trains are now used by the armies in the field. These are in use in Austria and Hungary, and also in Serbia; doubtless, also, in Germany and France. They are provided with sterilizing equipment, usually a refrigerator car into which steam is introduced. When baths are required the hot water is obtained from the locomotive. One of these trains has two cars with thirty bath-tubs each, two tank cars to supply the water, one car for undressing, four freight cars with clean linen, a sleeping car for the personnel of the train, and two or three cars for the disinfection of clothing. This arrangement permits 1,200 men in the course of ten hours to take a shower bath and have all their clothing thoroughly sterilized.

Even in the trenches it is possible to have needle shower baths. Cablegrams announce that the Philadelphia Committee of the American Ambulance has forwarded ten portable needle shower baths fighting on the Verdun battle front. They are much in demand, and 150 more are requested. Each bath outfit costs $120, and the needle spray is operated by means of pumps.

Combined Methods.—In addition to hydrologic forms of treatment, well-equipped spas provide massage, local dry heat by means of special electrically heated apparatus, and active and passive exercises by Zander apparatus. Electrotherapy also occupies an important place in the combined method of treatment.

In some of the larger French hospitals, notably the Grand Palais in Paris, which has been converted into a military hospital with 2,400 beds, all these measures are successfully applied. An experienced hydrologist from one of the French spas is in charge of that department. There is also a large outpatient service, where soldiers, chiefly officers, from all parts of Paris are treated; but the reports would indicate that better results are obtained with the in-patients, probably because daily treatment, sometimes extending over months, is required, just as we observe it in the case of physical treatment applied in civil practice.

According to Drs. Fox and McClure, local hydrological treatment is employed in a special manner for wounded limbs, especially for trophic lesions resulting from prolonged suppuration, chronic œdemas, swellings of the peri-articular tissues, and fractures of the articular ends of bones, and painful and adherent cicatrices. Such applications prepare the way for massage and movements, and render them easier and less painful. The arm or leg is placed in a local bath of running water (*balnéation à l'eau courante*). The temperature is hyperthermal, ranging from 40° C. to 46° C. and gradually increasing, and the duration from twenty to thirty minutes. The current is rotatory, of a strength that can be varied at will, and it can also be directed to any part of the limb. Such applications produce extreme vaso-dilatation and increased arterial circulation. In addition to these familiar effects, which are well seen in the treatment of stiffness and fatigue fever by hyperthermal baths, it is believed that "whirl baths," as they may be called, have a special action due to the movement of the water. The hydromassage, added to their high temperature, appears to have a marked sedative effect in relieving pain, and also promotes the lymph circulation and diminishes the effusions and swellings of soft parts. This form of bath therefore accelerates the retrogression of sub-inflammatory conditions. The same effects are not observed from baths of similar temperature in still water. Whirl baths are now always given before manual or mechanical treatment, and increasing importance is attached to them. At the annexe of the Grand Palais in five months 2,124 preparatory treatments in *eau courante* were given.

American Hydrological Resources.—It occurred to me that we ought to draw some lessons from European experience and make an inventory of our own resources, and at least see where we would stand in case we should be involved in a serious war. Conditions in the United States are very different from those in Europe, where, for the most part, the great spas are owned by municipal or national governments. I asked the Surgeon-General of the United States Army whether the subject of the use of spas for soldiers had ever been considered, and he replied that, as far as he was able to ascertain, no similar arrangement as, for instance,

that organized in England had ever been contemplated by the Medical Department.

Aside from the reservation at Hot Springs, Arkansas, which for over eighty years has been owned by the United States, and the wonderful thermal springs of the Yellowstone National Park, as yet unprovided with any medical establishment, the Government owns no spas. The State of New York, however, at an expense of over a million dollars, has acquired valuable springs and surrounding property in Saratoga, and is engaged in a praiseworthy effort to equip this spa for the general use of the public. This valuable property is now under the direction of the New York State Conservation Commission, and it is destined, we hope, to have a new era of usefulness.

We come, then, to the privately owned spring resorts where balneologic or hydrotherapeutic treatment, or both, is given.

In Maine we have Poland Spring, twenty-five miles from the sea-board. It has a small hydrotherapeutic department, and it is the only notable spring resort in New England. It has a capacity of about 600. In New York, besides Saratoga, already referred to, we have Sharon and Richfield Springs, Glen Springs, with its special treatment for cardiac cases, and Clifton Springs.

In Pennsylvania, Bedford Springs, about 300 miles from the sea-board; in Virginia, Hot Springs, Healing Springs, and Warm Springs, with a combined capacity of about 1,000, and an excellent equipment for balneologic treatment; the hydrotherapeutic equipment of the Chamberlin at Fort Monroe on Chesapeake Bay. The capacity of this resort is about 500, and it is on Government property. In West Virginia the White Sulphur Springs, thoroughly equipped, and with a capacity of about 1,200. This resort is about 250 miles from Washington and 300 miles from Chesapeake Bay.

In Indiana, French Lick, with a capacity of 1,000, well equipped with bathing facilities. Distance 600 miles from the sea-board.

In Michigan there is Mount Clemens, with numerous bathing establishments utilizing the saline sulphur water. Battle Creek Sanatorium, provided with a complete hydro-therapeutic department. Distance 628 miles from New York.

In Arkansas there are numerous establishments utilizing the thermal springs and a Government hospital for officers and enlisted men. Distance about 1,000 miles from the Atlantic sea-board.

Still farther west we have Glenwood Surings, in Colorado, and Arrowhead, Paso Robles, Napa Soda Springs, Paraiso Hot Springs, Klamath Springs, and other minor resorts. It is impossible to mention even the names of others, but they are for the most part open during the summer, and not very extensively or scientifically equipped. These resorts, however, would prove useful in case of operations on our Pacific coast.

It would be necessary in case of hostilities involving any considerable number of troops to have convalescent camps at which soldiers recovering could remain under military supervision until ready to rejoin. Because of expense and difficulty of undertaking long railway journeys, it is probable that the spas near our coasts would play a more prominent part than those far in the interior.

In the United States, as in England to-day, it would be doubtless possible to arrange for the use of privately owned spas for military purposes if that should ever be necessary.

There are some methods employed in European spas not very extensively used in this country. We do not make so much use of mud baths, of inhalations, and intestinal irrigations. These methods of treatment, common in European spas, especially on the Continent, are used to a very limited extent in the United States. Such measures require a special equipment, and probably will come into greater use in the future.

AGITOPHASIA ASSOCIATED WITH AGITOGRAPHIA.

By JAMES SONNETT GREENE, M.D.,

NEW YORK.

DIRECTOR, THE NEW YORK INSTITUTE FOR SPEECH DEFECTS; CONSULTING PHYSICIAN TO THE CHRYSTIE STREET HOUSE.

AGITOPHASIA is a condition of excessive rapidity of speech in which sounds or syllables are unconsciously omitted, slurred, mutilated, swallowed, or in any way imperfectly uttered, causing at the same time the speech accent to become distorted. The defect may be apparent or latent; that is, occurring from the first efforts at speech or appearing during the course of the development of speech. It is due to a pathological condition of the nervous system, usually the brain, and occurs in children up to the age of fourteen but occasionally persists to adult age.

It is of prime importance for normal speech that there be a coordination between the intended thought to be uttered and the word to be used. For conversational speech definite complete thought is necessary before the speech organs are set in motion for the desired words or sentences. It is always essential that there should be a complete personal supervision so that the desired words and sentences are correctly used.

In agitophasia, however, the mental action is so rapid and the desire to speak is so excessive that the speech organs cannot keep pace, there being a disproportion or a form of ataxia which is apparent, showing an incoordination between the desire to talk and the motor skill. In other words, one's ideas are so profuse and rapid that it is a physical impossibility for the vocal organs to express them clearly and distinctly in speech. The normal time correlation between speech and thought is lost. There is usually a pronounced lack of concentration; attention to what is heard is so superficial that on repetition many words are distorted, swallowed, and mutilated. This condition of agitophasia is sometimes referred to as spluttering, cluttering, tumultus sermonis, logorrhea, pararthria, and paraphrasia præceps.

Pathologically the motor speech area, Broca's convolution, is involved, so that motor vocal memories are distorted. There is an involvement of the nerves of some of the association or, projection

tracts running to the nuclei of the nerves governing the muscular action of the speech mechanism. Most cases of agitophasia are complicated by agitographia, a defect of writing which is similar to the speech defect present in the patient; that is,

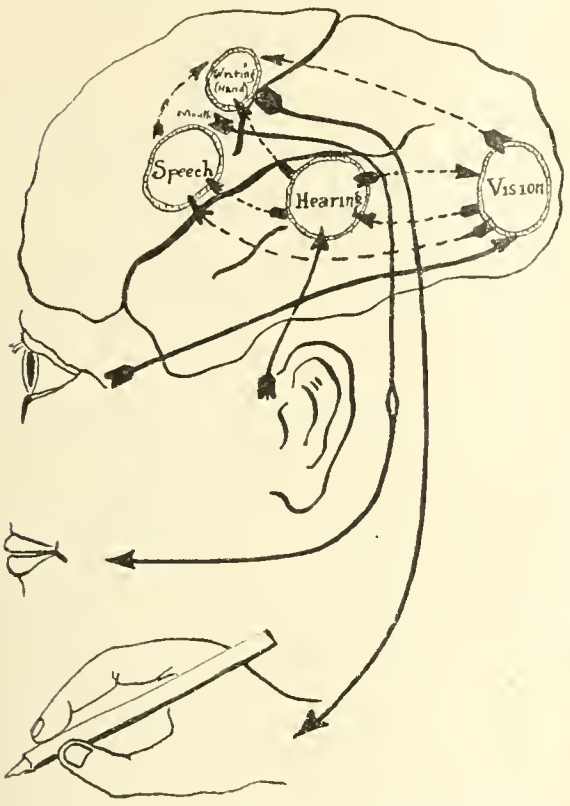

FIG. 1.—Diagram illustrating the speech zone of the left hemisphere. This scheme shows the centers involved in the mechanism of speech and the interrelationship between speech and writing.

just as the patient distorts and mutilates letters, syllables, and words in speech, he does the same when writing letters, syllables, and words. The reason for the presence of this writing condition is readily explained. The graphic motor word memories, being acquired last, are the least deeply imprinted and most easily disarranged. These memories are closely associated with the motor vocal memories, not alone through cerebral location but through function as well, this being exemplified when learning to write. On considerable practice we unconsciously repeat inwardly what we write.

Gutzmann states that there is a defect in the "ideogenic center," resulting in lingual ataxia. It is logical to deduce that this same condition exists in the writing, resulting in graphic ataxia. The ideation of a written or spoken word is based upon the association of the component syllables. If silent thought omits syllables and words in the construction of sentences they cannot be expressed in writing; therefore an impairment of this function of association naturally results in a pathological state, not only of spoken language but of written language as well.

Those who are feeble mentally very often show agitophasia to a marked degree. Mental coordination is lost, resulting in a torrent of half-articulated words on attempts at speech with normal tempo, although articulation is perfect when slowly performed.

The condition is either congenital or acquired (injuries, tumors, etc.). Retarded acquisition of speech and stuttering may be causative factors, and, as previously mentioned, according to Gutzmann, there is a defect in the "ideogenic center."

The psychic behavior of those suffering from agitophasia is shown in their restlessness and hasty disposition. They are impulsive, irritable, and sen-

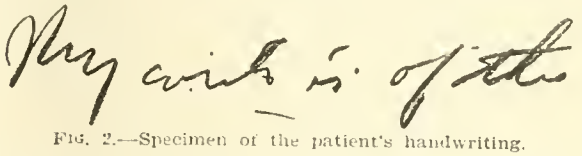

FIG. 2.—Specimen of the patient's handwriting.

sitive, and any disturbing influence is conducive to an exaggeration of their condition, leading to moroseness, melancholia, etc.

In these cases it is rather interesting to note that speech in the form of dramatic recitation or

singing is good, being almost normal. This no doubt is due to the fact that a new form of thought is not required, because through former repetitions correlation between thought and expression (speech) is almost undisturbed. Reading is more

or less disturbed according to the difficulty of the words.

The peculiarities of writing known as agitographia will be best illustrated through the cita-

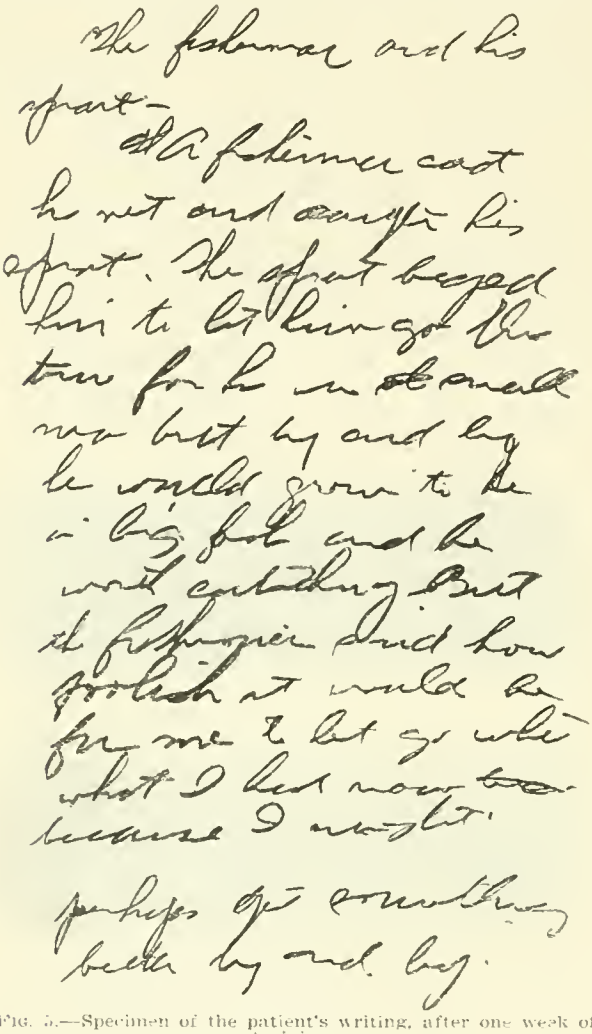

FIG. 5.—Specimen of the patient's writing, after one week of training.

tion of a case which recently came under my observation:

A young man, twenty years of age, was referred to me for treatment by an instructor in writing. This patient being fairly well educated was able to do general clerical work in an office except for one factor—his writing was barely decipherable. He, therefore, in order to improve his condition, decided to take a course in penmanship. Although he faithfully followed instructions he did not seem to make much progress. His instructor was unable to understand why an intelligent young man, like his pupil, should not show improvement. His writing bore the same characteristics that he had when he entered his class four months ago. He came to the conclusion that there must be some definite reason for the pupil's non-progress and since his attention was attracted to the fact that the young man's speech was abnormal, he referred him to me.

I found that he was suffering from the condition summarized above—agitophasia—which was complicated by agitographia. Just as in speech, he mutilated and swallowed sounds and syllables so he practically did the same thing in writing by the omission of letters or parts of the letters comprising the various words. We know that through the perfection of sensorimotor reflexes (both cutaneous and muscular) acting through the spinal cord, writing becomes almost automatic; but in this case, this perfection was interfered with. The following is a specimen of writing which was taken at the patient's first examination:

The patient states that when his father was a young man he had a habit of talking rapidly, which gradually disappeared in later life. There was never an abnormal writing condition present. His brother, the only other male member of the family, on the contrary, always suffered from agitographia, but never from agitophasia. The mother and three sisters never showed any signs of either condition. It is rather interesting to note that the condition affected only the male side

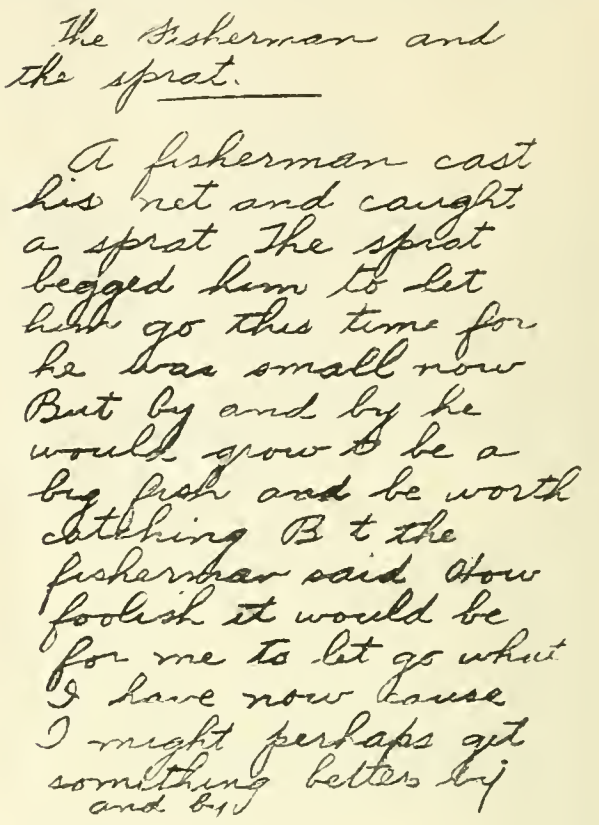

FIG. 6.—Handwriting of the same patient as shown in Fig. 5 after six weeks of training.*

of the family. The patient does not give a history of any condition since his childhood that could be connected directly or indirectly with his present state. No history of convulsions. He is in good health, mentally alert, but rather nervous and excitable. His speech and writing difficulties he has had since childhood. In his speech, when a sentence assumed a complicated form, his mind sometimes became so confused that he would offend against the grammatical and syntactical construction, inasmuch as he would repeat words or exchange them for others.

In his writing this did not occur, but he would, for example, disjoint syllables or letters—that is, he would miss a part of a letter, as the second curve of the letter N. He would half form letters in his hurry to get to the next letter and commit a few other vagaries which can be better understood by examining his style of penmanship than by reading the explanation. (See Fig. 2.)

His physical examination reveals no apparent abnormalities in development. Eyes—pupils regular, equal, central, react to light and accommodation, vision normal. Ears—negative. Mouth—teeth and gums in good condition; teeth in a state of lingual occlusion. Palate—high-arched and rather narrow. Tongue and throat—negative. Pharynx and larynx—normal. Laryngeal examination shows no evidence of spasmodic condition. Nose—nasal obstruction on right side due to the presence of a spur on the septum. Breathing—shallow, irregular, and of the costal type. Superficial and deep reflexes—normal, no abnormal reflexes elicited. Station and gait—normal. Slight ataxia of upper extremities. No tremors.

When writing for an extended period, the patient displayed a fatigue neurosis of the hand which was somewhat different from the condition commonly known as writer's cramp. In writer's cramp we have a spasmodic and disordered condition of the muscles concerned in writing, due probably to a functional perverted activity of the spinal motor centers, leading to disabilities in connection with the act of writing. In the spastic form of writer's cramp a spasm sets in in one or several

*The improvement in his writing kept pace with the improvement in his speech.

muscles that are being used. In some cases the flexors are affected; in other cases the extensors. The spasms may be either tonic or clonic. In the latter case the fingers, hand, or even the whole arm become affected with involuntary jerky movements. The arm aches and is sometimes tender.

In our case of agitographia there was only tension of the muscles of the forearm, which was due to voluntary inhibition in keeping his hand from running away. To quote the patient: "I must hold my hand back, if not, it will run away with the pen." He was unable to write for extended periods of time on account of this excessive muscular tension.

The kymographic tracings (Figs. 3 and 4) show the difference between muscular contractions of this patient's forearm when in the act of writing, and the muscular contractions of the forearm of a normal person when writing. The vibrations seen in the patient's record show definite tension or spasm irregularities. The vibrations seen in the normal person's record do not show spasm irregularities.

The diagnosis of this condition is sometimes confused with that of stuttering or lisping, but a complete examination of the patient readily yields a correct diagnosis.

The fundamental basis of all treatment in cases of agitophasia with or without agitographia is the inculcation of a sense of rhythmical slowness, both in speech and writing. This is best accomplished through suitable pedagogic exercises. High-frequency treatment, faradism, etc., are very beneficial. Surgical conditions present should be attended to. In the case cited, a right nasal spur was removed, giving the patient normal breathing.

In conclusion, if these cases are observed and diagnosed, especially at an early age, they readily respond to proper treatment; consequently, agitophasia, associated with or not associated with agitographia, can be classed under curable conditions.

ARTERIAL HYPERTENSION; SYMPTOMS, SIGNIFICANCE, SEQUELÆ AND MANAGEMENT.*

By HENRY FARNUM STOLL, M.D.,

HARTFORD, CONN.

ASSISTANT PHYSICIAN TO THE HARTFORD HOSPITAL, PHYSICIAN TO THE HOME FOR CRIPPLED CHILDREN AT NEWINGTON.

The importance of a discussion of cardiovascular disease will scarcely be questioned. At a time when we point with pride at the lowering death rate from diphtheria, meningitis and tuberculosis the mortality from cardiovascular-renal disease is steadily, even alarmingly increasing.

All of the time allotted to the discussion of this topic might with profit be devoted to any one of the subheads appearing in the title. However, it will perhaps be of more practical value to consider rather briefly all aspects of the subject.

We cannot really cope with the problem of hypertension until the underlying or real cause is determined. Nevertheless, by early detection and intelligent management we can usually prolong life and relieve more or less completely many distressing symptoms. We do not know how long hypertension can exist before symptoms are manifest, but apparently the factors which result in cardiovascular disease may operate for many years without sign or symptom.

Symptoms.—There are certain complaints which should immediately suggest the possibility of hypertension. These may be referable to the heart or to the kidneys; they may be cerebral in type or general in character. Headache and irritability, too often in a woman attributed to the "change of life," may in reality foreshadow a grave calamity, as a case I recently saw in consultation demonstrates.

Case I.—The patient, an unmarried woman of forty-eight, had had a stroke of apoplexy about twelve hours previously and died shortly after our arrival. She had always been exceptionally well, except that for several years she had been subject to *severe headaches* which were especially apt to come on *in the morning*, and for the past year she had been *irritable* and hard to get along with.

While many cases of hypertension are not accompanied by headache it is nevertheless a frequent symptom and is very often most marked on awaking.

The irritability of this patient quite naturally had been attributed to the menopause through which she was passing. It is worthy of note that both her *mother* and *maternal grandmother died of shock* at about sixty-five. Moreover *the patient's* next youngest *brother* aged 43, who denies syphilis, had a *slight stroke* of apoplexy a year ago.

It has long been known that certain families are prone to cardiovascular disease, and it is incumbent upon the physician to impress upon all members of such families the importance of having their blood pressure taken at least once a year, as there may be few or no symptoms though the disease is making steady progress. While it should be the routine to take the blood pressure on all patients it is especially important in that unfortunate group of sufferers we refer to as neurasthenics. An hemoptysis or an epistaxis may be the first symptom to send the patient with hypertensive disease in search of medical advice.

Case II.—A little over a year ago I saw a man aged forty in consultation who eighteen months previously, when apparently in good health, began to bleed from his nose. Notwithstanding that he received the usual treatment for *epistaxis*, the hemorrhage persisted for over two weeks and then, after subsiding for a time, recurred again. He was finally given injections of rabbit serum. About this time it was discovered that his systolic blood pressure varied from 190 to 215, and that his urine contained considerable albumin.

Case III.—A man of forty-eight was seen with Dr. Hanley in Stafford Springs. Five months previously he had had a *pulmonary hemorrhage*. He had been in good health previously, except (and please note the exception), that for the past *two years* his *endurance* has *not* been as *good* as formerly, and for several months he had noticed a *tightness across* his *chest* on extra exertion. Not alarming symptoms seemingly, but really of grave import, as four days following the hemoptysis the left side of his body became paralyzed. This hemiplegia cleared up completely, but was shortly followed by several other attacks. His systolic pressure varied from 190 to 240.

An interesting group are the patients who from time to time have attacks of spasm of the cerebral arteries.

Case IV.—For several years I had under my care an old lady over seventy who had a number of attacks of convulsions involving one-half of the body which were followed by more or less complete hemiplegia that

*Read at the meeting of the Litchfield County Medical Society, held at Winsted, April 25, 1916.

usually cleared up within thirty-six to forty-eight hours. Spirits of Glonoin dropped on her tongue—5 to 10 drops—would always stop the convulsions.

Another patient of advanced years, a gardener by occupation, had many attacks of paralysis, but frequently he would be at his work in the garden a few days later.

It is of interest that in neither of these cases was apoplexy the cause of death. The former died of sepsis from a bed sore following a fractured hip, and the old gentleman from an acute nephritis following prostectomy.

Sleeplessness, especially in the early morning hours, is often dependent upon vascular change and merits careful investigation. Dyspnea on exertion or paroxysmal and precordial pain occurring in a patient of middle age should always suggest cardiovascular disease. While directly attributable to failing cardiac muscle it is as a rule but part of a widespread vascular pathology.

Of about equal significance, though not so widely appreciated, are the digestive disturbances developing in individuals past fifty, often plethoric in type, who have hitherto enjoyed good digestion. They complain of a fullness and "pressure" below the sternum, are usually flatulent and most uncomfortable after their heartiest meal.

Nycturia and especially nocturnal polyuria are strong evidence against the integrity of the kidneys. Mention should also be made of visual disturbances and general indefinite wandering pains. Not infrequetly an orthopedist is consulted because of painful feet and legs.

As my practice does not include obstetrics, I have had no personal experience with the blood pressure readings in pregnancy, but their value has been thoroughly established. It has been demonstrated that hypertension frequently antedates the symptoms of toxemia and the appearance of albumin in the urine. Accordingly the physician who does not ascertain the arterial tension of his pregnant patients is not doing his full duty.

Case V.—A few months ago a young married woman was referred to me by her physician because of an *annoying cough*. No signs of pulmonary disease were found, but her systolic blood pressure was 280, diastolic 170. She had been pregnant three times. During the first pregnancy she was in excellent health and gave birth to a healthy, though not robust child. During the second pregnancy she developed a nephritis, and was blind for several days. This pregnancy was interrupted before the eighth month. No blood pressure readings were taken. It was again necessary for the same reason to interrupt the third pregnancy. Following this pregnancy the urine had cleared up and for this reason the patient had been assured her kidneys were all right.

The woman with hypertension and toxemia during pregnancy should be kept under very close observation for a month or two after confinement. Frequent blood pressure readings should be made and when the tension remains high we must conclude that a nephritis exists. Such a patient should not become pregnant again, as it is very probable that a toxemia will occur with possibly a fatal outcome.

Hypertension is so predominantly a condition of middle life and old age that we are not apt to realize that it is sometimes present in childhood. During the past year I have had four children with hypertension under observation. Two complained of morning headaches, but in the other two there were no symptoms. All were heredosyphilitic.

It is important to remember that the symptoms of an advanced nephritis in an old man may be due to the back pressure from an enlarged prostate which will promptly clear up after prostectomy.

Nature and Significance of Hypertension.—The blood pressure consists of *an essential pressure* which is required for life to be maintained and *an incidental pressure* which is dependent upon the different physiological processes and the various activities of our daily lives. The normal systolic is the essential plus the incidental, and for men and women of middle life is 150 and 140 respectively. Though dependent upon a number of things, the systolic pressure represents chiefly the cardiac force. The diastolic pressure is about 80 mm. lower than the systolic and is a measure of the peripheral resistance.

We are not yet in a position to say very much about the pulse pressure, that is the difference between the systolic and diastolic pressure, but the determination of the diastolic pressure is of great importance, as sometimes we find it considerably raised when the systolic pressure shows but little variation from normal. It is not so easily affected by various influences as the systolic pressure and is, in the absence of an incompetent aortic valve, a better indication of the condition of the arteries.

When the walls of the arterioles throughout the body have lost their elasticity and the lumen is diminished, the essential pressure must rise in order that the circulation be properly maintained. In the early days of blood pressure estimation this fact was lost sight of and attempts were made to get the pressure "normal" not realizing that the normal for the man with a granular kidney was higher than for his more fortunate fellow whose kidney was healthy.

Over and above this essential pressure is the incidental element that depends upon the normal functions of the body and the stress of our daily life. Sudden exertion, great and constant mental application, fits of anger, straining at stool, running for street cars, hurrying up stairs, etc., all raise our systolic pressure and the more or less constant recurrence of these sudden elevations of the pressure results in damage to the arteries, *especially if in the past they have been the seat of an inflammatory process.* As sclerosis develops the essential pressure rises and so a vicious circle is established.

Before the employment of kidney function tests many patients were seen in whom the kidneys could not be indicted from the examination of the urine, yet at autopsy nephritis would be revealed. As a result of the development of a number of different methods of investigation it has been shown that a persistent hypertension is practically always indicative of change in the kidneys. Even when the picture is that of diabetes, the hypertension is due to an accompanying cardiovascular condition rather than to the diabetes. However, the kidney arterioles are not alone involved, for careful examination has revealed that the condition is a widespread disease of all the smaller arterioles. While definite knowledge is lacking, it seems probable that the pathological process which ultimately manifests itself as hypertension disease has its inception years before symptoms occur.

Though an immense amount of work has been done in an endeavor to find the causal factor of hypertension, there is no definite agreement among clinicians. Alcohol, tobacco, lead poisoning, syph-

ilis, intestinal autointoxication, the acute infections of childhood and chronic foci of infection all have their champions. The first three certainly have no part in the causation of the cardiovascular disease so common among women of comfortable circumstances. No clear case has been made against intestinal autointoxication as the universal cause, though it is possible that it is sometimes a factor.

It is conceivable that a chronically diseased tonsil or an abscess about a tooth of many years' duration might result in arterial disease. In fact, I have been told of a case where the extraction of a tooth and the cure of the abscess was followed by a fall of pressure. Yet nearly every ward patient has pus about his teeth, but only a few have hypertension.

There is some evidence, both clinical and experimental, that the acute infections may cause arterial degeneration which may be followed by a certain degree of sclerosis, yet it has never been established that the pathology started by scarlet fever, diphtheria, etc., will continue to advance for years after the disease has been clinically cured. We do know, however, that the *Treponema pallidum*, whose predelection for the arteries has long been known, quietly and unobtrusively causes widespread destruction of vascular tissue. Markedly sclerosed, even calcarious arteries have been found in children with hereditary lues who have had none of the acute infectious diseases.

However, be the underlying cause what it may, it is very apparent that the stress of life is unquestionably the direct or immediate cause. The death rate from cardiovascular-renal disease is much higher in large cities where the pace is most rapid and higher in this country than in England and Wales, where the life is more tranquil. In fact, in Great Britain the increase has been practically negligible.

Sequelæ.—The best compilation of what surgeons call "the end results" have been made by Janeway. Half of his hypertensive patients had died by the end of five years, and of those living half died during the next five years. That is, only a quarter lived over ten years. Women live on the average longer than men, notwithstanding that they have pressures fully as high. This is probaly due to the fact that they are better able to save themselves when symptoms develop.

Gradual cardiac failure is the cause of death in about 30 per cent. It is important to recognize this group because they must be treated as cardiac cases irrespective of the hypertension.

About 20 per cent. die of uremia, while apoplexy causes death in 15 per cent. Angina pectoris and intercurrent infections each cause death in approximately 7 per cent. of instances. In women death from angina and from edema of the lungs appears to be rare. Apoplexy or uremia is the cause of death in most cases in which pressure is persistently above 200. Angina and, strangely enough, gradual cardiac failure are not apt to follow these very high pressures.

Severe morning headaches, nocturnal polyuria and visual disturbances indicate that death will probably result from uremia, and in about 75 per cent. of cases within six years. Cardiac symptoms, of which dyspnea is the most constant, suggest death from gradual cardiac failure. Janeway found that a rapid and continuous loss of flesh was an unfavorable symptom.

Management.—We may roughly divide our patients into two classes. The first comprising the individuals who come to our office, as their symptoms are not sufficiently urgent to make them give up work. The other group comprises those in whom the disease is further advanced and who are seen at their homes or in the hospital.

In the first group it is particularly important to study each case thoroughly in order that we may ascertain if possible what the incidental factor of the hypertension is. It may be prolonged mental application without adequate periods of relaxation; it may be too many cigars, or it may be too long hours and a general unhygienic régime under which the patient lives.

Inquiry as to his habits should always be very thorough, as a readjustment of his life is necessary, but it should be brought about with the least possible violence. To tell an active business man with moderate hypertension that he must immediately give up all his business is speaking thoughtlessly and unwisely. He will not take kindly to crocheting, neither will he sit under a tree and write sonnets. With care, however, we can usually rearrange his habits so that a great deal of strain is taken off of his arteries.

The "noon hour" should be multiplied by two. After the midday meal, which should be the chief meal, rest in a recumbent position for an hour is desirable. If the patient can sleep a part of that time so much the better.

If the physician explain to an intelligent patient, that as the arterioles lose their elasticity and their lumen diminishes, the blood pressure must of necessity rise to maintain the circulatory balance, he will materially lessen the anxiety that the term high blood pressure occasions. If the physician further explain the incidental factor of arterial tension and enumerate its chief causes he will readily obtain his patient's cooperation, which is so essential in the management of these cases.

The hypertensive individual must first of all stop "hustling." He must school himself to say, "There will be another car in a few minutes" when he is late at breakfast. If he must climb stairs, deliberation should characterize the act. If he be a really remarkable man he may learn to control his temper, for there are few things more injurious to diseased arteries than bursts of anger.

The individual with but a slight degree of hypertension, free from morning headaches, and who is eliminating a good amount of phthalein in two hours (50 per cent. or over) should not be put on a milk diet nor told to give up all meat. A moderate amount once a day is desirable.

It has long been known that overeating is distinctly harmful and it is particularly so in this class of patients. The heaviest meal had best be taken at midday and the supper be simple. The importance of complete relaxation one or two days of each week cannot be overestimated, as fatigue is cumulative. It is important that the patient take several warm baths each week, have a daily evacuation of the bowels and a cathartic once or twice a week, but too active catharsis will be followed by faintness and weakness.

One cannot deduce that because the urine contains no albumin the integrity of the kidney has been preserved. When the amount of urine passed during the night exceeds the amount voided during the day and when the gravity is persistently low or "fixed," one must conclude interstitial changes have already begun. The phenolphthalein kidney

function test is the only one of the function tests that can be readily performed by the general practitioner and it corresponds quite accurately with the more complicated estimations of the non-proteid nitrogen in the blood.

It is important, however, to appreciate that the amount of phthalein eliminated at any time is an estimate of the kidneys' ability to excrete that drug only at that particular time and does not *per se* warrant an absolutely favorable or unfavorable prognosis. The kidneys may improve or the trouble may extend within the next few weeks. It is desirable in all cases of hypertension to ascertain from time to time how the kidneys are functionating, as occasionally the diminution in function may precede serious symptoms.

During the winter months hypertension patients should avoid all unnecessary exposure, as even a mild infection may result disastrously.

Vasodilating drugs are not usually called for and are often harmful. In certain cases they will unquestionably relieve symptoms, but their routine employment as soon as the patient comes under observation should be discouraged. When the tension is very high a prompt venesection may be lifesaving.

I have frequently obtained marked relief from sleeplessness, nervousness and headaches by the use of potassium iodide and mercury either by injections or inunctions, though the Wassermann test was negative.

In the second class of individuals, where the kidney and heart are not longer able to adequately do their work, the patient must be in bed.

Digitalis is nearly always required irrespective of the blood pressure and fears of a higher tension resulting are groundless. Not infrequently a combination of potassium iodide and digitalis will give results not obtainable with either used alone. A low phthalein output and an increase in blood nitrogen regularly accompany this stage of the disease, and the diet should be low in protein and sodium chloride.

If the patient be very edematous only 800 c. c. of milk in twenty-four hours should be allowed (Karrel diet). This has the advantage of being low in protein and sodium chloride.

When compensation is reestablished carefully regulated exercises are to be instituted.

The distressing dyspnea that so often attends the final days of hypertensive patients can be controlled only by morphine. The temporary improvement from a good night's sleep following its use is often very gratifying, and it should not be withheld when the end is near.

75 Pratt Street.

MILK AND COMMUNICABLE DISEASES.*

By Linsly R. Williams, M.D.

Albany, N. Y.

Deputy Commissioner of Health, New York State.

An outbreak of communicable disease was traced to consumption of raw milk as far back as 1854. Since that time there has been a large number of epidemics traced to the consumption of raw milk, and in each instance it was found that there was, or had been, a case of specific communicable disease upon the dairy farm where the milk was produced or among employees handling the milk. There is now a large amount of literature on the subject of milk-borne diseases and numbers of epidemics of septic sore throat, typhoid fever, diphtheria and scarlet fever have been found to be due to the use of raw milk which had been infected with the organisms of these diseases.

The work of the British Royal Commission on the Study of Bovine Tuberculosis and that of Theobald Smith, Ravenel, and Park, in this country, have conclusively demonstrated the fact that bovine tuberculosis may be transmitted to man and that from 5 to 15 per cent of all cases of tuberculosis in children are of bovine origin. During the past year and a half there have been reported to the State Department of Health at Albany over 800 cases of communicable diseases causing thirty-seven deaths which were due to outbreaks of scarlet fever, septic sore throat, diphtheria and typhoid fever. In each epidemic the cases occurred largely upon the milk route of one dairy. A careful study of these epidemics has shown in each instance that the cause was due to the presence of an individual affected with one of these diseases upon a dairy farm supplying the milk to the persons who became ill of the disease.

The use of raw milk has not generally been considered in this country as a source of danger, but for many years physicians in Continental Europe have regularly recommended the use of boiled milk for the feeding of children and infants. About twenty-odd years ago there was introduced into this country a change in infant feeding caused by the boiling or pasteurization of milk. As time wore on and the demand for the use of this milk became more widespread, physicians reported unfortunate results and a few cases of scurvy were described among the many thousands of children using it.

With the increasing difficulties of introducing an adequate supply of fresh milk several of the larger milk dealers in our great cities conceived the idea of heating their milk in order that they might keep it for a longer time. These dealers then began to pasteurize their milk. In the pasteurization of ten or more years ago it should be remembered that it was performed by what is known as the "flash system." The "flash system" consists in rapidly passing milk over a heated coil raised to a temperature of 167° or more F. When this system began to be more generally applied, objection was made to it by health boards and physicians, for the following reasons: The health boards objected because they felt that this would enable unscrupulous milk dealers to sterilize filthy and disease-infected milk; and that in milk which had been heated in this manner the lactic acid bacteria would be destroyed and the milk, instead of souring, would become putrid and would be consumed without the consumer knowing that the milk had spoiled, as it would not have the well-known sour taste. Physicians objected on the ground that the consumption of this milk by infants and children would result in large numbers of cases of scurvy. The opposition was nowhere greater than in the city of New York.

Six years ago the city of New York adopted the general chlorination of the entire water supply of the city. This did not produce the expected diminution in the amount of typhoid fever in the Greater City and a more thorough study of the cases of typhoid fever resulted in the discovery of several widespread epidemics of typhoid fever upon the routes of one or more milkmen. By tracing this

*Read at the Annual Conference of New York State Health Officers, Saratoga Springs, June 7, 1916.

milk to its source, cases of typhoid fever and typhoid carriers were found upon the dairy farms which had infected nearly the entire milk supply of one or more dealers. These and other epidemics soon convinced the authorities of the city of New York of the importance of pasteurizing the entire milk supply of the city.

In making a study of the subject it was found that milk pasteurized by the flash system had a certain number of disadvantages. Some of the milk in passing rapidly over the heated coil soon formed a film which varied in thickness so that in some places the stream of milk passing over the coil was subjected to varying degrees of heat. Careful examinations made showed that such a method of pasteurizing did not always destroy the pathogenic bacteria. Later investigation showed that such a high amount of heat was unnecessary in order to destroy all pathogenic bacteria, and it was ultimately found that a temperature of from 142 deg. to 145° F., if maintained for a period of 30 minutes, would entirely destroy all pathogenic bacteria.

Certain objections, however, are still made to pasteurization as follows: (1) Feeding of pasteurized milk to infants may cause scurvy; (2) pasteurized milk has a stale, flat or boiled taste; (3) pasteurization of milk diminishes the amount of cream in a bottle of milk; (4) pasteurization increases the cost of milk; (5) pasteurization devitalizes the milk and reduces its food value. Each and every one of these objections can be readily met.

The mortality records of the city of New York, where over 90 per cent of the milk supply has been pasteurized by the holding method, show no increase in the number of deaths from scurvy. Even if there may be a possible increase in the number of cases of scurvy, it is fairly generally admitted by children's specialists that the danger from milk-borne diseases is far greater than the danger of scurvy, and that by the proper administration of orange juice to infants beginning at the sixth month or earlier, the occurrence of scurvy will be prevented.

The second objection, as to the change in taste of pasteurized milk, has a certain foundation because, if milk be heated to above 155° F., it will have a somewhat boiled or flat taste, but if milk be properly pasteurized within the temperature limits now usually prescribed by cities and States, there will be no alteration in the taste. Simple experiments will readily demonstrate this. Many persons have made the simple test of sampling first raw and then pasteurized milk and have not been able to distinguish between them. Pasteurization properly performed produces absolutely no change in taste. If there is a change in taste it is always found that the milk has been heated to a higher temperature than is necessary.

It has been stated by some observers that there is a diminution in the amount of cream when milk is pasteurized. This complaint is made by the consumer. A complete series of experiments carried out in the laboratory of the New York City Department of Health by Kilbourne showed that there was a diminution in the volume of butter fat, which rose to the surface in milk which had been heated to a temperature higher than is necessary through faulty pasteurization, and that within certain limitations the higher the temperature to which the milk was heated the smaller the amount of cream which rose to the surface. But even at the higher temperature there is a diminution in the amount of cream which rises of only 10 per cent. It should be definitely understood, however, that even though the cream line be diminished there is absolutely no diminution in the fat content of the milk, and therefore no diminution in the nutritive value.

It must be admitted that the cost of machinery and the cost of operating a pasteurizing plant is considerable, but the actual cost is far less than one cent per quart of milk and in some communities in New York State properly pasteurized milk is now being sold at the same rate as the raw product, and the concerns selling this milk are making money from the sale of their product.

A number of experiments have been made in feeding pasteurized milk to young, growing animals. It has been found that calves and other smaller animals, when fed on pasteurized milk, will thrive just as well and gain in weight just as steadily as when fed upon the raw product. An experiment carried on some years ago under the direction of Drs. Park and Holt of New York City in the feeding of infants, showed that infants fed at the breast had fewer cases of illness among them and did better than infants who were fed upon properly modified milk. In two groups of infants fed on modified raw milk and modified pasteurized milk there were fewer cases of diarrhea and fewer deaths among those fed on pasteurized modified milk than among those fed on raw modified milk.

Another interesting fact is that the cities of New York, Boston, and Chicago have for from three to five years had a large majority of their milk supply pasteurized, and during this period there has been a large diminution in infant mortality and in the number of deaths from diarrheal diseases.

Conclusions.—It would seem, therefore, that the chief objection to the pasteurization of milk is that it is a change from the long-continued habit of the use of raw milk and that, although there may be a slight increase in the cost of milk that has been pasteurized, yet the health insurance that is given in preventing a larger number of epidemics of milk-borne infectious diseases is far more important than the small sum paid for this protection.

It must be said, however, that there are still a number of medical men and health officers who contend that pasteurized milk is nothing more than cooked filth, but sanitarians and health officers should insist that pasteurized milk must be pasteurized clean milk and that every precaution should be taken to insure the milk being pasteurized in clean containers. The method of pasteurization should be supervised, for if the milk is improperly pasteurized complaints will come, and they will be made against the whole process of pasteurization rather than at the slip in the method. But if pasteurization is carried on intelligently and under the direction of qualified health officers it will give the quality of milk that the people demand, and will result in a diminution in the amount of communicable diseases.

Practical Value of the Schick Reaction. — Arthur Sprenger concludes that the Schick test is of positive value in determining the susceptibility of a patient to diphtheria, and also in differentiating doubtful membranes of the throat. It shows that in some cases passive immunity is of short duration. The author does not, like others, find that immunity is a familial characteristic. The test insures a saving of antitoxin, for it has shown that less than 50 per cent of children are susceptible to diphtheria. Carriers give a negative Schick reaction.—*Illinois Medical Journal.*

THE ROLE OF DOCTORS' SONS IN THE LINCOLN ADMINISTRATION.*

A CONTRIBUTION TO THE PSYCHOLOGY OF GOVERNMENT.

By WILLIAM BROWNING, Ph.B., M.D.,

BROOKLYN, N. Y.

PROFESSOR OF NEUROLOGY, LONG ISLAND MEDICAL COLLEGE.

THE important part taken by doctors' sons in the regimé of Lincoln does not appear to be generally known, if, indeed, it has ever been recognized. Nor, in the case of most of these participants, do the customary biographical sketches give any indication of the medical parentage.

Except as casually included in medical history and memorials, that side of medical life which may be termed the Sociology of the Profession has been but little studied. Kelly has explored the relation of physicians to botany, and doubtless there have been efforts in one or another direction that deserve mention.

Such a sociology represents a more democratic phase than does isolated achievement or individual prowess. And it might naturally be expected that in America it would have both a larger field and a sounder appreciation than elsewhere. There is now an abundance of material on the sociological side concerning the profession itself. Though in its entirety a large subject, many parts are sufficiently complete in themselves to admit of separate presentation.

In the historic interest of our members, to offset attacks on our calling, and as a genetic study, the gathering of material of this order has a larger warrant than merely to gratify curiosity.

Since the days of the Revolution no period in our country's history has been so stressful, so fraught with danger, and so seriously in need of wise guidance, as that of the Civil War. The leader of that time was Lincoln. The superior quality of his wisdom in action and in the selection of his immediate supporters is recognized. It consequently becomes a matter of deep interest to size up the mental atmosphere of his surroundings, and to see if any clear element is recognizable. That he had a true genius for gathering and utilizing opponents as well as presumable congenials renders any element in his make-up and entourage the more striking.

It is easy to pick out the men who officially and personally stood next to him, distinctly more so than most others, and this group became more pronounced as his administration progressed. At least four of these were his own choice; and doubtless he was consulted about the selection of some of the others. For the present purpose it is only necessary to give an outline sketch of each, sufficient to show his standing, relation and paternity. Most interested readers can fill in much from memory. The cases in point are as follows:

1. Judge David Davis, the private adviser and legal friend of Lincoln, who accompanied him in both these relations on the momentous journey in February, 1861, to Washington, and remained in that capacity unofficially. He had not acquired at that time all the national reputation that came later (U. S. Judge, Senator from Illinois, and in 1881-3 acting Vice-President); yet he proved fully worthy of the confidence placed in him.

In the Republican national convention of 1860 Judge Davis (as delegate-at-large from Illinois) had secured the nomination of Lincoln, and after the election "was a chief councillor of the President."

Judge Davis was a son of Dr. David Davis, a physician of Cecil County, Mo.

2. John Hay, Lincoln's personal private secretary, in later years U. S. Secretary of State. Nicolay, a German by birth, was the chief executive secretary, but Hay was the one in close confidential relations, perhaps more so than anyone else during the full period of Lincoln's administration. He was very young for such a responsible post, only 23 years of age at the start, though admitted to the bar.

Hay was born in Indiana, the third son of Charles Hay, M.D. (1801-84), a native of Kentucky and "a prosperous physician."

3. Then came the Vice-President, Lincoln's running mate in the campaign of 1860, the Hon. Hannibal Hamlin, ex-officio president of the U. S. Senate. His term did not expire until March 4, 1865. Hamlin was a lawyer, had been speaker of the Maine House, M.C., U. S. Senator, and Governor of Maine. Subsequently he was our minister to Spain. He was born at Paris, Me., the son of Dr. Cyrus Hamlin.

Dr. Hamlin was born in Massachusetts (1770), was a practising physician, and at times had filled a number of positions of local responsibility.

4. Solomon Foot (1802-66); never much in the public eye, and now little heard of. Yet as president *pro tem.* of the U. S. Senate (Feb. 16, 1861, to April 26, 1864), as floor leader of that body, head of its most important committees, potentially in line for the Vice-Presidency, and chairman of arrangements for the Lincoln inauguration in 1861, he was an invaluable aid at the transition time and for much of the Lincoln period. He was the most prominent advance agent who held over to the new era, a man of mature years and wide training, who come into his heritage of responsibility on the withdrawal of part of the members.

Foot had been professor of "natural philosophy at the Vermont Medical School, Castleton, 1827-31," lawyer, Speaker of the Vermont House, State's Attorney, M.C. (1836-42 and 1843-7), U. S. Senator (1851-?), and railroad president.

He was a native of Vermont, the son of Dr. Solomon Foot. His father, a physician, born in Connecticut, died when the son was barely nine years old.

The two secretaryships, of State and of War, were at that time unofficially, if not formally, recognized as the leading two cabinet portfolios. In this case the long term of service of the occupants show each to have been *persona grata* to the President. Everyone who recalls that period or is familiar with its history is well aware of the fact that in the general estimation these two men were Lincoln's main reliance and his most representative cabinet heads.

5. William H. Seward, Secretary of State. Seward had previously served as Governor of New York and as U. S. Senator. Though he had been the chief competitor for the Republican Presidential nomination in 1860, he gracefully accepted and admirably filled the statesman's position in Linco'n's cabinet. He was the ranking member of that body, remained through Lincoln's whole administrative career, and subsequently engineered the purchase

*In part from a paper read November 16, 1915, before The Book and Journal Club at Baltimore.

of Alaska. He was born in Orange County, N. Y., the son of Dr. Samuel Swezy Seward.

Dr. Seward came from Connecticut. In later years he "combined medical practice with a large mercantile business."

6. Owing to the peculiar conditions of the time, the cabinet officer next in importance was the Secretary of War. From Jan. 15, 1862, on, this post was filled by Edwin M. Stanton (who had previously been the U. S. Attorney-General in the cabinet of President Buchanan). By the necessities of his very important position, by continuance of service, and by personal association he was, next to Seward, the cabinet officer in nearest affiliation with Lincoln. Stanton was a lawyer by training, born in Ohio in 1815, and the son of Dr. David Stanton.

His father, "a prominent physician," was of Quaker stock, and came from an eastern State. He died while his son, Edwin, was a child, although not until he was some years old.

7. On the legislative side highly important for the administration is the Speaker of the Congressional House. From early 1863 on this position was filled by the Hon. Schuyler Colfax. He was a member of Congress from 1855 to 1869, and subsequently (1869-73) Vice-President of the United States. He was born in New York City, March 23, 1823, the second child of Schuyler Colfax, Sr.

The father was born in New Jersey, Aug. 3, 1792. He married Hannah D. Stryker, April 25, 1820, and died of tuberculosis, Oct. 20, 1822, five months before the son was born. Small wonder that there is a paucity of details regarding the father. An old account states that he studied medicine, and then took a bank position to earn means for starting in practice. Another biography indicates that he studied medicine in 1810-12 with Dr. David Marvin of Hackensack, N. J. Studying medicine with a preceptor instead of at a medical school was the more common way at that time. His widow disclaimed any knowledge of this, except that he and the doctor were old friends. But, as she was speaking long afterward, had been married in her sixteenth year, had but a short married life with him, and that some time after the date assigned for his studying, her lack of information on this point hardly counts. The positive evidence is sufficient to warrant including the name of the son in the present list.

Taken together, the seven men named were, next to Lincoln himself, the leaders in the executive and even the legislative work of the U. S. Government during that period. They were closest to him in official and personal relations, and, with the balance of the cabinet, constituted his special lieutenants, advisers, and administrative guard. It is consequently a notable fact that the seven were all sons of physicians, and this is the more striking as it is without known precedent. Of course, periods of such gravity and far-reaching interest are in themselves rare.

To read theories into or out of history is known to be as unprofitable as theorizing in medicine. Still, we have finally come to the stage in medicine where it is possible to have profitable theories. And the more embryotic science of history may yet find activators.

To offer any generally acceptable explanation of this peculiar occurrence is hardly possible. To say that it was a mere coincidence is the simplest and most customary way. That, however, offers no explanation, and it is against experience and every theory of probabilities.

To suppose that it was definitely planned, as by one mind or some coterie, is quite as improbable. No incentive or reason appears for such a vast scheme. Nor is there any evidence or suggestion of such an effort. Nor, finally, can we see any way by which it would have been practically possible.

A further view comes up that cannot be as readily decided. Everyone is invigorated by a stimulus that appeals to him. Of all the educated and trained classes and in the community, the medical is the only one that in any real analysis stands heartily and with conservative wisdom by the whole people. Did, then, the sentiment, the national and intensely democratic spirit of the time rouse these men, because of their inherent attitude, more than it did others of possibly equal ability in the community?

There is an alternate way of looking at the matter that is rational and appeals more to medical minds. This grouping of prominent men was doubtless accidental, in the ordinary acceptance of that term; that it was so in the psychological sense is hardly imaginable. The drift of circumstances and the compelling necessities of the time had simply forced the selection of those specially suited to the extreme demands of the situation. Because it was involuntary and natural makes the occurrence the more significant.

We can grant that this combination of talent was just a coincidence—and yet draw a long bow. It affords strong evidence—perhaps the strongest possible—of the superior intellectual value of medical training and heredity. And those who attribute thereto an educational quality of basic character may see a direct verification in this development at a national crisis.

Besides his leading official mainstays it may be noted that Lincoln's leading competitors in the national campaigns of the period afford parallel illustrations. Seward has been mentioned above.

8. A leading opponent, both before and in the campaign of 1860, was Stephen A. Douglas, LL.D., United States Senator from Illinois. And it was with Douglas that Lincoln had just previously held the series of public debates that so stirred the nation. On the popular vote at the election Douglas was next to Lincoln, though behind Breckenridge and Bell on the electoral count. "Socially they were on friendly terms," and Douglas even held Lincoln's hat during the inauguration at Washington.

Douglas was born in Vermont, the only son of Stephen Arnold Douglas. The father, "a native of New York State and a prominent physician," died suddenly when his son was two months old.

9. In the campaign of 1864 Lincoln's opponent was George B. McClellan, General-in-Chief, U. S. A. General McClellan was a native of Philadelphia, the son of George McClellan, M.D. Dr. McClellan was born in Connecticut in 1796 and was widely known as a surgeon and professor of surgery.

That all talent of this kind was not exhausted in the first line trenches, to use a phrase of to-day, might be shown by innumerable examples; that, however, would not affect the main "exhibit."

It is natural in this relation to turn back for comparison to that other time of national tribulation, the Revolution. The surprising number of medical men who were signers of the Declaration of Independence has long been a matter of note. There were at least six with medical training, four

of them practitioners. And in close correspondence with this is the fact that the Mecklenburg declaration in 1775 was written by Dr. Brevard, a surgeon.

At the Lincoln period, nearly ninety years later, the mantle of the fathers may be said, professionally speaking, to have descended to the children.

LESIONS OF THE FRONTAL LOBES.*

By EDWARD MERCUR WILLIAMS, M.D.,

Sioux City, Iowa.

Lesions of the frontal lobes, particularly of the mid and prefrontal zones, are always rather obscure in their symptomatology.

The cases presented here, while allowing very little doubt as to the diagnoses, show interesting points, as well as demonstrating how easily one may be misled in considering confusing or obscure signs as due to distal pressure or cutting of transcortical fibres. In two of these patients (B and C) symptoms thus attributed to general pressure or invasion were afterward found to have been caused by an additional growth in one and by two extra growths in the other.

The rapid but late onset of the symptoms in case A, four months after an injury which gave very slight disturbance at the time of the accident, is rather out of the ordinary, and the later course of the disease gave several points of interest, such as voracious appetite, impotence, incontinence of urine and feces, and a peculiar emotional state very difficult to describe accurately. The man had constantly an expression of fear or anxiety and always spoke as though he looked for something unexpected to happen. Just before his operation he was found out on the lawn in his gown and barefooted, although he had not protested against the operation at any time. He simply said at this time that he was afraid, but did not resist further or refuse to be operated.

The confusing picture in case C can be easily understood when knowing of the presence of the two other growths in the prefrontal and opposite parieto-occipital regions respectively. The voracious appetite was a pronounced symptom in all the cases of tumor or hemorrhage, whereas in several cases of frontal lobe abscess, either proven or suspected, but not included in this paper, the loss of appetite was marked, this being in all probability due to the profound toxemia.

In case C this excessive appetite and thirst was so pronounced that the man would cry and scream as though in pain before a nurse could bring him a glass of milk after he had asked for it. No doubt the loss of emotional control had a great deal to do with these outbursts. I later found out that the man had "spells or fits of excessive hunger," as the relatives called it, for a number of years previously.

Frontal ataxia is not very common, but was present in case A and case B, and oddly enough contralateral in one and homolateral in the other, being so marked in the former as to have previously led to a diagnosis of probable cerebellar involvement.

In this series, including the two frontal abscesses and a case of frontal hemorrhage above mentioned, but not described in detail, the optic atrophy as described by Kennedy was not found in any instance. However, there were changes to indicate an older and more advanced process in the involved side in a tumor and abscess and a hemorrhage and a changing of the apparent intensity of involvement in the case with multiple tumors.

Tests of the sense of smell were negative in all cases but one, where there was a definitely greater involvment on the affected side.

This brief series has led me to conclude that a localization as to the side involved in a frontal lesion can be made only guardedly from such signs as slight disturbance of mentality, upset of emotional control, intensity of optic neuritis, or disturbance of smell, unless definite motor or speech disturbances are present. In three instances, not included here, where in addition to the usual general signs of brain tumor and above-mentioned symptoms of frontal involvement disturbance of motor speech was present, an operation failed to reveal any lesion in that locality, unless possibly too deeply subcortical to be found.

Case A.—Farmer, age 40, a patient of Dr. V. B. Knott. Four months previously he had been kicked in the forehead by a horse. He was dazed for a few minutes, then went on with his work. He had several attacks of severe headache and some slight general feeling of weakness, but otherwise no disturbance up to a few days ago, when he began to suffer intensely from headache and he noticed a great increase in his appetite and thirst. He rapidly became impotent, and during several days in the hospital developed incontinence of urine and feces. When walking the man would wander, or totter toward the opposite (left) side, and in his attempts to eat and dress himself and perform finger, nose and heel, knee and pointing tests, the ataxia in the left was very pronounced. There was also a certain amount of weakness difficult to differentiate from ataxia. Double neuroretinitis, possibly slightly more advanced on the diseased side.

The deep reflexes were about normal in the contralateral side (left) and less active in the homolateral, or right side. Plantar reflexes normal. The emotional state has been described, a peculiar expression of fear or anxiety and "far away," or vacant, expression. The patient seemed able to remember and figure well enough, yet he gave one the impression of a certain degree of mental impairment, or dullness. Operation and removal of an old clot from the right, mid and prefrontal region epidural, with complete recovery.

Case B.—Mrs. K., age 35, patient of Dr. R. Q. Rowse. Headache, more or less, for a number of years, but during the last five weeks more constant and severe. Sight gradually diminishing in this time, particularly within the last three weeks. Nausea and vomiting often during this period. The sexual desire is diminished. For some weeks she has eaten and drunk a great deal more than her normal amount. Right ptosis was present for a couple of weeks, clearing up entirely. There seems to be a possible history of slight forgetfulness, but this is very doubtful.

At the time of the examination the patient did not seem to show any particular mental disturbance, except some lassitude easily attributable to the headache and nausea, etc. Left pupil was larger than right and reacted less to light and accommodation. Ptosis was present in the left with paralysis of the other oculomotor muscles on that side. The right internal rectus was also slightly involved. Sight was diminished to almost complete blindness. There seemed to be a slightly better ability to recognize objects as shadows with right eye and in right field of right eye and possibly of left eye. Advanced "choked disc" in both eyes with evidence of an older process of the left. There was ataxia of the left arm and leg as shown by the usual tests, the deep reflexes of both arms were absent, also he knee jerks and the ankle jerks were very weak, more so on the left. Plantar irritation gave normal response on left and a very active upward and inward drawing of the foot on the right. A very slight twitching of the right wrist extensor muscles occurred at intervals of a few seconds, almost constantly. When first tested the sense of smell was gone on both sides, possibly due to acute coryza. Tested two days later,

*Read by title at the forty-second annual meeting of the American Neurological Association at Washington, D. C., May, 1916.

showed a definite difference of the two sides, diminished on one side and almost entirely gone on the side of the tumor (left).

At operation the left prefrontal area was exposed and a tumor resembling a melanosarcoma, but later proving to be a sarcoma, was found involving a large portion of the prefrontal lobe. The patient died in several weeks and the autopsy disclosed an additional sarcomatous growth on the under surface of the right temporal lobe, well back toward the occipital area. This may have had something to do with the indefinite, but suggestive, hemianopsia.

Case C.—Farmer, age 47, patient of Dr. V. B. Knott. About four weeks prior to my examination, patient found right arm and leg partially paralyzed upon awakening. As he had suffered a great deal from rheumatism he attributed it to that and in a few days the condition improved so that he could go about again. I was informed later that the patient had really been more or less handicapped in the use of his right arm for two years or more. The headache, which was pretty severe, also cleared up, as did a partial facial paralysis. He also had a facial paralysis on the left nine years previously. In the last week or so the headache became more severe and patient had nausea and vomiting, not cerebral in type, but increasing in frequency and severity.

In the examination I found the pupils equal and reacting normally. No ocular muscle disturbance. The examination of the fundi showed a neuroretinitis with hemorrhagic streaks and spots, resembling very much albuminuric retinitis more active on the right, veins not particularly engorged nor arteries changed in caliber, discs indistinct. Seemed to be some weakness of both facial nerves in entire distribution, could wrinkle right brow fairly well, however. The right arm showed impaired strength for all the coarser and finer movements, though they were all possible. The same was true of the right leg. Left side was normal. Arm reflexes more active on the right, also the knee jerks. Ankle clonus and positive Babinski on the right. No sensory changes either from touch or position anywhere. Heart sounds feeble and slow, about seventy per minute. Pressure right arm 135-90, left 125-82. Diminution in amount of urine, high colored and loaded with dark granular casts and albumin. A tentative diagnosis of nephritis was made at this time with request for further information about the case in view of the great possibility of brain tumor.

Three weeks after this examination I again saw the patient. He had had a number of unconscious spells of a few minutes' duration with twitching of both shoulders and to some extent the right hand. Had shown lack of emotional control; as already mentioned, would grasp a glass of milk, when brought to him, in both hands and gulp it down greedily. Several times there were outbursts of foolish laughter with no apparent cause. There had been several motor aphasic attacks lasting only a few minutes. Vomiting and headache had become much worse, almost constant, in fact. The patient did not seem to have the same degree of intelligence as formerly, although the rest of the family denied this possibility. Paralysis of right arm and leg almost entirely cleared up, particularly the right leg; plantar reflex on the right and left at this time normal. No clonus. Knee jerks below normal on both sides. Urine had shown neither casts nor albumin for a couple of weeks. Diagnosis of tumor in the mid-frontal or post-frontal region on left was made. At operation a tumor the size of a pigeon's egg in post-frontal region and about an inch and a half below the cortex, about on a plane with the arm center, was removed. It was a clearly defined encapsulated growth of carcinomatous nature.

The man became practically well a couple of weeks after the operation, then rapidly became worse, and the old area was opened and no hemorrhage found; a decompression was done in the opposite side and excessive bulging of the dura found. Patient died several weeks later and the autopsy revealed two other growths similar in shape and a little larger than the removed growth, one further forward in the pre-frontal area on the same side and on a plane about one-half inch lower. It was entirely subcortical and clear cut. The cortical indentations were very poorly developed or atrophied in the region of the frontal pole. On the opposite side (right) a similar growth just back of the occipito parietal juncture and also about an inch subcortical was found.

443 Davidson Building.

EYE INJURIES AS RELATED TO WORKMEN'S COMPENSATION.*

By F. D. Gulliver, M.D.,

New York.

In my talk this afternoon I shall endeavor to relate some points bearing on eye injuries, which I hope will not only be of interest but of assistance to you in dealing with these cases which come under the Workmen's Compensation Law.

1. I shall first speak briefly of the function of the eye and describe how the amount of visual power is measured and expressed.

2. Of the most common eye injuries showing part of eye affected, and shall explain certain technical phrases so that reports on eye injuries can be more easily interpreted.

3. I shall describe the best means of shortening the period of disability and of preventing permanent disability after eye injuries have occurred.

4. I shall endeavor to point out that malingerers and exaggerators exist among eye claimants; the probable number of the same and the means of detection.

5. I shall draw attention to compensation for partial defects of vision; how various States regard partial defects of vision, and their basis for making awards for such defects, and shall make a comparison of awards in the various States with those of the New York Industrial Commission.

6. And, finally, I shall deal briefly with the answers to any questions regarding the eye, and invite full discussion of my remarks.

The eye is the only organ in the body whose function can be accurately measured. In cases of partial loss of function, the remaining amount can be determined by standard tests and expressed in fractions of normal vision. Such being the case, eye injuries should be the simplest of all injuries from the standpoint of adjusting a fair scale of indemnity to the injured. For instance, in the case of a crushed hand or foot, there would naturally be a considerable diversity of opinion as to what fractional amount of usefulness still remained. But, as stated before, in partial impairment of sight the amount of vision remaining can be accurately determined and definitely stated.

How is the Amount of Visual Power Determined and How Stated? Visual acuity, amount of vision, visual power and vision are synonomous terms. Vision is usually the term employed. Vision is measured by standard test figures, or test types of fixed dimensions. These test cards are used throughout the world and agreed upon by all doctors as the standard and accepted means of determining the amount of vision. And if there is one point on which doctors would all agree, it is this point.

The ability of the patient to distinguish the letters on the cards is expressed in fractions—the distance at which test card is placed being the numerator, and the distance at which letters displayed subtend an angle of five minutes, the denominator. Test cards are always placed at a distance of twenty feet, and the cards are properly illuminated either by daylight or artificial reflected light. Then, with a patient at a distance of twenty feet who can distinguish only the top letter of card, vision is stated as 20/200 or 1/10 of normal. If he reads the second line, 20/100 or 1/5 of normal,

*Delivered before the New York Claim Association May 5, 1916.

and so on. Of course, it is taken for granted in persons not seeking remuneration for an alleged injury that they are using their full visual power.

Cases of suspected malingerers or exaggerators I will speak of later on.

Now, in a case of eye injury, what you men want to know is: (1) What is the amount of vision present? (2) Was defect of vision due to injury as claimed? (3) Is vision improved by glasses? (4) Is defect of vision permanent?

Eighty per cent. (80 per cent.) of eye injuries resulting in defects of vision involve the cornea. The pupil, or pupillary area, is the central portion of the cornea through which we see. Any injury affecting this part of the cornea naturally results in loss of vision. Unless injury does affect the pupillary area, there is no impairment of vision. Injuries to the cornea in most cases leave a portion of the cornea opaque or cloudy. This condition is commonly expressed by the following terms, which all mean the same: scar of cornea, macula of cornea, nebula of cornea. So that when you get a report from a doctor on an eye, stating that there is a scar macula, or opacity of the cornea, and that vision is 20/50, you will know that there is an opaque or cloudy condition of the cornea and vision is 2/5 of normal.

The next most common injury to the eye, impairing vision, is injury to the lens. When the lens has been injured a cataract develops, which is also called traumatic cataract. Cataract means that the lens loses its transparency and becomes opaque. In all cataract cases there is always almost total loss of vision. Now, in many of these cases, the cataract can be removed, and by putting a proper lens before the eye the sight is restored to one-half, or even to normal vision. Such improvement in the sight of an eye after the removal of a cataract is usually of no practical advantage to the injured, for the following reasons: It is impossible to wear the cataract glass on the injured eye and still use the other eye at the same time. This is because the cataract glass over one eye produces double images and great discomfort. Of course, in the event the sight of the other eye becomes impaired, the injured can use the cataract eye alone for visual purposes. Commissions rule, however, that in a case where cataract has been removed, although the injured may have good vision in the eye by using a cataract glass—for reason already stated, namely that the injured will have to depend on the uninjured eye for visual purposes—such a case is entitled to compensation for total loss of the eye. I believe this ruling a fair one in a compensation case when viewed from the standpoint of loss of efficiency to the injured. In a liability case, I would view the matter quite differently.

Foreign bodies, especially steel, penetrating the eye are of rather common occurrence, and are important injuries. In any case where there is any possibility of a foreign body in an eye, it should have an *x*-ray examination without delay.

The retina is the innermost coat of the eye, and is very important because it is the part of the eye by means of which we are able to see. Injuries and inflammations of the retina are called retinitis, and are usually associated with marked impairment of sight. In the retina are often found evidences of a general syphilitic condition and of other general diseases, such as Bright's disease, diabetes, thickening of the arteries, etc.

Now, as to malingerers and exaggerators.—In my work of examining eyes of persons seeking compensation, I have found that fully ten per cent. pretend there is defective sight in one or both eyes when vision is normal, or exaggerate greatly the amount of defective sight. Of course, the reason why persons with eye injuries try to deceive the physician examining them is that they believe that he cannot disprove their statements in regard to the amount they are capable of reading on the test cards. Very happily for insurance companies this is not the case. Very rarely will a claimant simulate total blindness of one eye. They always elect to lessen greatly the amount of vision actually present. The best means of detecting and exposing exaggerators and malingerers is to fight them with their own weapons, namely deception. There are many simple rules and tricks to employ that expose the cleverest of this class of claimants. All methods of detection are based on making the claimant believe that he is seeing with the good eye, when in reality he is using the injured eye. This is accomplished by different arrangements of glasses and prisms. Examining these cases and detecting false claims and statements affords one both diversion and amusement, and the satisfaction of knowing that the individual has not accomplished his dishonest aim.

I wish to state in this connection that in all eye cases with defective vision, I have the injured come to my office twice before making report as to amount of vision. It is not fair to the injured or the insurance carrier to make a statement on such an important matter as this until I have obtained complete and conclusive evidence. In cases of malingerers, I have them report to me three or even four times in order to use different tests in different ways and under different conditions before making a final report on the case.

Furthermore, in this connection, I would say that when reports of eye specialists do not agree as to amount of vision in a particular case, it is not a question of opinion as to amount of vision, because the same tests are universally used. The explanation is that the injured on one examination intenionally or unintentionally did not use the full visual power of the eye. One can easily understand how a person might be nervous under first examination by a physician and not need the test card to an amount equal to the full visual capacity.

I have a case in mind where I found vision to be 2/3 of normal. The medical examiner for the commission requested an examination by another specialist. This physician, famous in his profession, reported the vision as 2/7, and the man was awarded for total loss of the eye. Subsequently, I examined the man and found vision to be 2/3. Now, of course, the physician designated by the commission stated what he believed to be a fact in regard to amount of vision; but the claimant was not using full visual power. I might add that the above case has been appealed.

What are the best means of lessening duration of disability and preventing permanent disability (partial or total) after eye injuries have occurred? In the first place, you must know that there are a considerable number of persons awarded compensation for a defect of vision which has existed previous to the date of the alleged injury. The only certain way to exclude such cases is to have all applicants for work examined by a physician,

and in a case of defective sight not to give employment to such applicant.

Fully appreciating that it is not practicable to observe the above measure in all cases, how then can a person having an existing defect of sight and receiving an injury to that eye be prevented from receiving compensation to which he is not entitled. The only means I know of are: (1) To get immediate notification from assured of all eye injuries. (2) To make an immediate investigation of the case. (3) To have injured report at once to an eye specialist for examination, or, in case where the injured cannot or will not report for examination, have an eye specialist visit the injured in his home or hospital. I cannot emphasize the importance of above procedure too strongly. It is of the greatest moment if you would avoid paying false claims. In many cases I am not asked to examine a case until several months after the injury. How am I to tell them whether the injury, as alleged, caused the loss of sight? Whereas, if I had seen the case a week, or even two weeks after injury, I could say whether the injury on the date alleged caused the condition, or whether some previous injury was responsible for it.

My suggestions as to an immediate examination apply to the treatment of eye injuries as well. I know of a large number of cases where sight could have been saved if properly treated by a physician skilled in this particular branch of medicine. The following cases coming under my observation are only a few examples: A man with a piece of steel in his eye was treated for two months by an osteopath—by rubbing or massaging his back. Another with the same condition was treated by a doctor for a month with electricity. One case of cataract was operated upon and the eye subsequently removed before the insurance company was notified. Another case where the eye was badly injured, the sight was wholly destroyed and serious inflammation was present. The treatment indicated was removal of the diseased eye. This eye was allowed to remain until the good eye became affected by sympathetic inflammation. Result, total blindness—*i.e.* total permanent disability.

Awards in partial defects of vision in one eye. The law specifies the amount for total loss of one or both eyes and leaves it to the commission to fix a lesser amount when the defect is only partial. The majority of cases by far with which you have to deal are partial defects of sight of one eye. It is to these cases that I will devote my closing remarks.

From the point of view of an eye specialist, I have long felt that the awards for partial defects of one eye by the New York Commission were not in proportion to the actual loss of function, and greatly in excess of possible loss of efficiency or earning power to the injured. In order to learn how the commissions of Germany, Austria and States in our country regard these cases, and on what basis they make awards, I have addressed a copy of the following letter to all States and territories—about thirty in number:

Dear Sir:

For the purpose of comparison, I am endeavoring to get from the various States in which Workmen's Compensation is in force, the basis on which their boards or commissions make awards in cases of defective vision resulting in partial loss of sight.

In most jurisdictions the law gives the amount of total loss and leaves it to the Commission to fix a lesser amount when the loss is only partial. Have you any fixed rule on which to base the award in partial loss of sight, or do you estimate the loss on a percentage basis?

In order to simplify the matter and arrive at a basis for estimating awards in all cases, I think it would be well to start with award for total loss of sight of one eye. Then, taking the case of an individual with normal vision in one eye and a laborer, or of such occupation as does not require good binocular vision to efficiently perform his work, would you be kind enough to inform me on what basis or to what extent you would consider the above case compensable, when having the following fractional amounts of vision in one eye: 20/200 (1/10); 20/100 (1/5); 20/70 (2/7); 20/50 (2/5); 20/40 (1/2); 20/30 (2/3).

I have received replies from all States and reviewed the laws of Germany and Austria. In Germany and Austria, and in all States of our country where there has been occasion to rule on such cases, the basis of award is as follows: Individuals with remaining vision of 1/10 or less of normal in the injured eye are compensated as for total loss. Where vision is more than 1/10, awards are made on a percentage of total loss. The above basis applies to all occupations.

Let us compare awards of other States with those of New York. Our commission takes into consideration the vocation or work of the injured in considering the amount of award. This is only just and fair, and in my opinion a commendable act of that body. But, of course, the question naturally arises, if one class of workmen is to receive more for partial loss of vision, why should he not receive more for total loss?

The New York Commission rules that in a case where remaining vision of the injured eye is 1/3 or less, the injured is entitled to compensation as for total loss. Now, with 1/3 of the amount of average normal vision remaining, an individual has a considerable amount of sight. For instance, if a man had only one eye and in that eye had 1/3 the amount of normal vision, such man would be able to go around the city, recognize different objects and read medium-sized type in the newspapers. Of course, with two eyes and normal sight in one, the condition is far different. However, the New York Commission regards an eye with 1/3 remaining vision as totally lost.

More important still, a person with total loss of one eye cannot see objects on that side; that is, he has lost one-half of his binocular field of vision. A person with 1/3 vision still retains the extent of his field of vision. Again, with total loss of one eye, the injured is greatly handicapped by an absence of the appreciation of the dimension of depth when looking at objects. This power is accomplished by using both eyes in conjunction. With 1/3 vision, one can use the injured eye in conjunction with the good eye and enjoy the great advantage of stereoscopic vision.

Our commission has ruled in cases where the injured eye has remaining vision of 2/3 the amount of normal vision, the claimant is entitled to compensation for 1/2 loss of the eye. In amounts of vision between 2/3 and 1/3 of normal vision, the award is determined largely by the vocation or work of the injured. The above awards apply to laborers and those not requiring particularly good visual power. In cases of mechanics and those persons requiring good vision, the award may be increased at the discretion of the commission.

Before establishing a basis on which to make awards for defects of sight of one eye, a knowledge of the proportion of persons who never acquire normal vision in both eyes should be had. Without error of refraction corrected, *i. e.* by

glasses, the percentage is from 30 to 40. Again, acuteness of vision is largely a matter of training, and laborers whose sight requirements are moderate, and illiterates who never do any reading, are apt to have subnormal vision when tested on cards with letters and numbers with which they are unfamiliar. Now, a person not needing particularly good vision, as obtains in many employments coming under the act, can perform his work very efficiently with 2/3 vision in both eyes. Of course, with normal vision in one eye and 2/3 vision in the other, there could not possibly be loss of efficiency on account of sight.

I direct especial attention to the ruling of the Commission of this State where injury to one eye with remaining vision of 1/3 compensation is awarded as of total loss. In Germany, Austria and all other States to which my attention has been called—and I have made searching inquiries—the loss must equal or exceed 9/10 to secure compensation for entire loss. It is important and interesting to consider the basis and merits of the two rulings.

It is clear that with 1/3 remaining sight the field of vision is not destroyed, whereas where the remaining vision is but 1/10, the field of vision is practically gone. This is equally true of the stereoscopic vision. It seems unfair that with the field of vision and stereoscopic vision practically intact, compensation for total destruction should be given. This view is taken in all jurisdictions other than in this State. It is self-evident that total destruction is one thing, and 1/3 remaining vision with a field of vision and stereoscopic vision remaining is quite another thing, and compensation in the two cases should not be identical.

My aim is to make clear that the general ruling giving total compensation where 1/10 of vision remains, with practical loss of both field of vision and stereoscopic vision, is far more equitable and should be adopted in this State. Likewise, it is unfair to one who has suffered total loss of an eye to receive no more compensation than one with 1/3 of the sight remaining and with the field of vision and stereoscopic vision practically unimpaired.

As the percentage of remaining vision can be ascertained by measurement, compensation should be given to the extent of the percentage of loss of vision. This is the general rule outside of this State. But in New York, where the remaining vision is 2/3 of normal, compensation is given for 1/2 of the loss of the eye. Were it impossible to measure with accuracy the amount of vision destroyed, an arbitrary ruling giving 1/2 compensation where remaining sight is 2/3 might be justified. Where the actual percentage of loss is readily ascertained, equity and justice would indicate that the compensation be placed at the actual loss.

It is furthermore to be considered that in this State the financial compensation for total and partial destruction is greater than elsewhere. The measure of damage is greater, and the basis of compensation is more favorable to the injured. There is no pretense that there exists in this State a greater value in eyesight than elsewhere, or that the partial or total destruction should be measured more favorably to the injured, especially since, as above explained, the extent of loss may be accurately measured and correspondingly compensated without arbitrary ruling.

Speaking from the standpoint of both the injured and assurer no fair adjustment for partial loss of sight can be reached without a consideration of the vocation of the claimant. A study by commission of the visual requirements of each class of employment coming under the act, and a classification formerly made with a percentage of award for each class, in my judgment, would be the fairest to the injured and to the insurance carrier.

105 West Seventy-second Street.

PRIMITIVE MEDICINES.

A SHORT SKETCH ON EMETICS AND PURGATIVES.

By J. Barkley Percival, M.D.,

Paramaribo, Dutch Guiana.

Our cats and dogs pick up carrion now and again with the consequence that their stomachs get out of order. Instinct impels them to strain for relief by vomiting the obnoxious matter. Housewives hear the hawking and drive them out of doors, if possible before it comes to the worst! The animals often get nausea and pain, but cannot get immediate relief until they have taken an emetic of grass. The discomfort or pain drives them to take medicine.

Primitive man was like the dog in his habit of picking up meat wherever he found it and no matter how tainted it might be. He would also taste strange fruit, some of which might be poisonous. When the painful results drove him to do something he chewed herbs which he had learned by former experience caused vomiting.

Our children eat unripe and rotten fruit and come crying to their mothers with their hands pressed against the painful part. The mother finds the child retching and gives large draughts of tepid water, sometimes putting her finger down the child's throat until the desired result is obtained.

These are examples of the beginnings of medicine; we may call them fancies but they are reasonable. When man first began to take medicine is a riddle which will probably never be solved, and yet the problem is worth considering. Pliny, whom we consider one of the ancients, said he admired the industry and laborious research of the ancients in finding out by experiment the medicinal properties of plants. We also have to thank, not only the Chaldeans, Egyptians, and Greeks, but the East Indians and Americans as well. The real origin of medicine, however, goes back to primitive man when his impulses were mainly instinctive.

What happens when poisonous crabs or sprawns are taken? I can state from personal experience. There is retching, colic, cold sweats, and a general feeling of collapse. Something must be done to relieve the symptoms and the feelings indicate an emetic, a purgative, and a warm bath. The most urgent is the emetic, but vomiting often takes place without assistance. The principle of all medicine should be to assist nature and this was acted upon by the primitive American, who followed the same course as our cats and dogs by chewing some herb as an emetic.

There is one herb peculiar to America which must have been discovered long ages ago, for it is widespread and never truly wild. This is tobacco, which possibly may have been the primitive emetic. That it is powerful everyone will admit, especially the boy who has suffered from his first smoke. To chew the green leaves is even more likely to cause vomiting than the smoke. Every smoker knows

the effect of a tiny bit of tobacco when accidentally swallowed.

Those who only know tobacco as smoked, or taken as snuff, are possibly not aware that it has been taken internally as a diuretic in dropsy. It is, however, so very powerful that in many cases it produces nausea; it is also much used externally as a sedative for aches and pains as well as swellings. The medicine man generally drinks tobacco water when he is going through his ordeal. He also uses it to bring on a trance when carrying on his work.

Smoking is probably a late development of its use and a strictly American discovery. Possibly the sedative effects of tobacco water were agreeable to those who enjoyed getting drunk, but the nausea and sickness were too much even for the Indian. It probably led to smoking, which gave the pleasant feeling so well known, and no nausea after the smoker became accustomed to it. The smoking habit was unknown in the old world until introduced, but it so quickly spread that some have doubted whether it did not exist in India before the discovery of America. The evidence, however, will not admit of this.

A well-known emetic is the kaka-baballi or buck-puke, which is much used by the native cross-bred races in South America. As far as I can gather it is free from the defects of tobacco. Other emetics include bullet tree bark, red mora, and others with only Indian names.

The wild coffee or myamya root is Indian as well as creole; it seems to be a very violent emetic, only used in extreme cases of bilious fever. The so-called white lily bulb is another severe emetic. The creole emetic most commonly in repute is the palse ipecacuanha.

It may be stated that most intoxicants are also emetics. The Indian's piwarri is decidedly so and beer is not far behind. The most repulsive stage of drunkenness goes to prove that all intoxicants are emetics when first taken.

It is a sound principle to take medicine when there is something which impels us to do so and this impulse might be given by the spirit drinker as a reason for taking up the habit. But, as all medicines are poisons and should be used to assist nature only when absolutely necessary, there is no rational excuse for their being taken habitually.

Emetics and purgatives are both indicated when some poisonous meat or berry has been taken. There are both retching and colic, indicating plainly that the somach and bowels must be relieved. This is provided for by several remedies, especially those nausious herbs which cannot be retained if chewed or swallowed without disguise. On this account most of the nastier purgatives are now used in pills. Primitive man did not know how to make a pill and, therefore, many of his medicines acted both ways. The negro often asks the druggist for pills to work both ways; his medicine must "do him justice." He has not the idea of assisting nature, but desires to take her by storm. Whether the Indian also likes strong purgatives I am not quite sure, but we may expect that his stoicism in pressure of pain means that he is glad to know that the remedy is fighting the disease. A gentle laxative would probably be unsatisfactory to the man who wants to fight a disorder.

Emetics and purgatives are very numerous, especially among the creole remedies. One of them is well known in gardens as Allamanda cathartic and is an Indian medicine of great potency. Acosta said long ago that there are a thousand simples in America fit to purge, and though I have not come across anything near a hundred still the purgatives are too numerous to deal with in this article. I think that a mere list would be of little value and anything more would take up too much space; I can, therefore, only give a few examples.

The creoles use carrion-crow bush as a purgative, and like many others of its class it sometimes acts as an emetic. The leaves are used fresh in decoctions and are more powerful than senna, to which it is closely allied. Other species of Cassia have similar properties, and we may safely state that the genus contains many good purgatives besides the two species known as senna.

An allied plant called "Doctor Doodles" or Barbados Pride is probably a valuable medicine, for it supplies from its different parts mild and drastic purgatives to suit young chidren and strong men. The flower buds may be used as a gentle aperient for children, the open flowers for adults, the leaves and pods as stronger purgatives, the bark of the stems yet stronger; and the root is so drastic as to be dangerous.

This suggests the fact that we have something analogous in the Natural order *Euphorbiaceæ*, to which the castor oil plant belongs. We can get milkweed as a gentle laxative and go on to belly-ache bush, castor oil, physic nut, and sand-box, which last is dangerous. In connection with the reactions of plants we may state that butterflies and moths appear to feed on a number of allied species of similar qualities. They choose by the odors and tend to confirm deductions made from botanical alliances. In cases just mentioned we have a division of the bean family with qualities like senna, and the Euphorbias more or less resembling castor oil.

Jalap is represented here by a substitute, the four-o'clock or marvel of Peru, the roots of which were once used as an adulterant of the real drug. It is not quite so strong as jalap, but the roots are so similar that a novice could hardly tell them apart.

Aloes is grown in boxes by the creoles and the juice sometimes used as a purgative; it is, however, too nasty for general adoption. Its use is generally limited to external dressings for "rose" and other swellings.

We have already stated that colic is one of the symptoms of poisoning; many vegetable poisons are drastic purgatives, decidedly painful because of their griping. Among them I may mention the frangipanni, the mudar or ladies pin-cushion, and the good-luck. These are very dangerous. We have also in cultivation some of the cucumber family, such as Karyla and luffa, the active principles of which are similar to that of colocynth; these are not worth considering.

The tendency of late years has been to reduce the heoric doses once so common. We still find, however, that some of the creoles must have griping purgatives, for mild aperients will never "do them justice." If the women dealt only with themselves it would not be so bad, but unfortunately their children are often injured by drastic cathartics. Even when they use castor oil they often give an adult's dose to a child. We may safely state that as a rule too much medicine is taken everywhere. When the primitive man took an emetic or purgative and got relief he did not go on with the medicine for weeks as some people do nowadays.

We may ask whether any of these medicines are worth retaining. In regard to emetics we may say that they are hardly needed except in the treatment of poisoning. If a purgative is required it is generally safe to take a small dose of castor oil; this was formerly made in the Colony from seeds grown here and could be so again. A good substitute for senna is the Barbados Pride, the leaves of which can be dried and kept for some time.

The foregoing facts point to certain conclusions from which we can form a tentative theory of medicine. It was once supposed that the constituents of plants were made for the use of man; we know that they are for the benefit of the plants themselves. Indian corn and wheat contain what we may call baby's food, for the starch and other things support the young plant until it is strong enough to feed itself. Man has utilized the stores of plant food for his own purposes, but they were not secreted for his use.

We can apply the same principle to medicine. Through the ages there has been a grand struggle between plant and animal, the results of which we can see every day. Certain animals feed on certain plants and the plants resent this by secreting noxious juices, some of which are poisonous to most animals. But there are always some that become immune and are able to feed on the poisons. A certain amount of protection is gained, probably enough to insure the preservation of the species, but it is never complete.

Disorders and diseases are common to plants as well as animals. They are largely due to the wonderful provisions for eliminating the weak and unfit. As soon as the plant or animal is injured there is a grand struggle between the recuperative powers and those scavengers that are always ready to dispose of the dying and dead. If there is enough internal power to heal or overcome the sickness there is a recovery, otherwise death ensues. If the animal or plant can do anything to help the healing process it is well, but little has been done by others than man. What we see in dogs and cats is suggestive, and possibly wild animals may take similar emetics.

The principle, as we see it in nature, is that an impulse is given to do something when we suffer pain. In fact pain is the warning note; like hunger, it plainly says take what is suitable. Proper foods were always known, but not proper medicines. There has been more improvement in the preparation of foods than in that of medicine, but great progress has been made in both. There is, however, apparently a fault with the latter; people take medicine when not really sick. This is not helping Nature, and in many cases it hampers the recuperative powers.

On this principle I must condemn tobacco smoking and spirit drinking, even though I condemn my own pipe. They are medicines and should be used only when we are sick. However, I suppose people will go on smoking and drinking, for we are not always rational.

Opinion Evidence.—In an action against a railroad for injuries in a derailment, where the road contended that the plaintiff did not receive the injuries through the derailment, but from disease, it was held that testimony of a physician that in his opinion there was no injury to the cartilages of the knee joint, and that when the plaintiff received the injury, of which she told him there was a fracture of one or more of the synovial cartilages, was inadmissible.—Jackmann v. St. Louis & H. R. Co. (Mo.) 187 S. W. 786.

Medicolegal Notes.

Insufficient Evidence of Malpractice. — Action was brought against a physician for damages on account of injuries sustained by the plaintiff while a patient at a maternity hospital for the purpose of confinement, by reason of the breaking off of the glass tip of a vaginal douche while it was inserted in the vagina of the plaintiff, and permitting the broken fragments to remain imbedded in her flesh without informing her thereof. On appeal from a judgment for the plaintiff it appeared that the plaintiff was attended by the defendant during her confinement in a large maternity hospital; that shortly after her confinement she suffered from the effects of what was subsequently found to be the presence of fragments of glass in the wall of the vagina; that she was discharged from the hospital without the discovery of such condition; that thereafter she consulted the defendant and was treated by him because of her continued suffering; that the doctor made several examinations, and attributed the trouble to the failure of the stitches to heal which were necessarily taken in the person of the plaintiff after the birth, or to the fact that the gut used in sewing up the torn parts had not absorbed or assimilated in the plaintiff, and calcareous matter had accumulated.

The court said: "It would hardly be profitable to enter into a discussion of the facts of this case in this opinion. The plaintiff has completely recovered. The only negligence claimed against the defendant is for his delay in making such an examination of the vaginal cavity as would disclose the foreign substance thereafter found. Two experts of standing have sworn in behalf of the defendant that it would have been poor surgery to have made such an examination as would disclose the existence of foreign substance before the time that it was actually made by the defendant. One expert, on behalf of the plaintiff, has sworn that such an examination ought to have been made three months before it in fact was made. It is always easy, after the cause of an injury has been found, to look back and say that that cause should have been sought for. To my mind the jury failed to give proper force to the fact that this defendant had never had the slightest cause of suspicion that any foreign substance could be causing this trouble. Every fact surrounding the case and its treatment would constitute almost proof of its absence. The breaking of the glass of a vaginal douche within the vagina is a circumstance so rare as not to have been reasonably contemplated at any time by the defendant, and for failure to anticipate this most unusual occurrence the defendant has been most unjustly charged with a substantial money judgment, and, what is worse, with a stain upon his professional fidelity. That this verdict is clearly against the weight of evidence I have no doubt whatever."

Judgment for the plaintiff was reversed and a new trial ordered.—Rogers v. Voorhees, New York Appellate Division, 157 N. Y. Supp. 330.

Tuberculosis Hospital a County Purpose.—In an action to enjoin the erection of a tuberculosis hospital by a county, the New York Appellate Division holds that the erection and operation of a hospital is a proper county purpose, although the hospital takes some pay patients. It has never been held that the incidental revenue from board, or from special care, deprives such an institution of its charitable character.—Smith v. Smith, 160 N. Y. Supp. 574.

Testimony as to Professional Service Where Patient Has Died.—Under New York Code Civ. Proc. Sec. 829, prohibiting testimony of an interested person as to a transaction with a decedent, in a physician's action for professional services against executors of a decedent, testimony of the physician that he attended decedent professionally was held inadmissible.—Kennedy v. Mulligan, ,New York Appellate Division, 160 N. Y. Supp. 105.

Improper Cross-Examination of Medical Witness.—In an action by a husband for damages for personal injuries to his wife, one of the elements of damages was the bill of a physician who had had principal charge of the plaintiff's wife after the accident. He had testified to the amount of his bill, and was asked on cross-examination if he expected to get it paid out of the litigation. The question was held improper.—Jolman v. Alberts, Michigan Supreme Court, 158 N. W. 886.

THE ETIOLOGY OF EPIDEMIC POLIOMYELITIS.

THERE has been no epidemic of recent times that has so excited the attention of the whole populace as that which has prevailed during the past summer. The youth of the patients affected, the rapid spread of the disease, the high mortality, and the mystery which surrounded the methods of transmission, combined to add to it a peculiar terror, which was not lessened by the rigid and often unnecessary quarantine regulations which were adopted by some localities. The causative organism may be said to have been discovered by Flexner and Noguchi, but the epidemiology of the disease was certainly not on a satisfactory basis. The publicity given to the epidemic naturally attracted many investigators, and the result of their work has begun to appear in articles which, if the information which they contain is correct, have increased somewhat our information as to the cause and spread of poliomyelitis.

The work which was done in the New York Hospital Branch had already received a certain amount of attention, but the first authoritative description of the results accomplished was given by Dr. Rosenow at a meeting of the New York Academy of Medicine on October 5, as reported in the MEDICAL RECORD of October 21. In this report, Rosenow summarized briefly the work done by him and his associates, Towne of Boston, and Wheeler of New York. They followed the lead which Rosenow established in his work on the elective localization of streptococci in the study of rheumatism, endocarditis, gastric ulcer, and other conditions, and were able to isolate a pleomorphic streptococcus which, as a result of their extensive animal experiments, they felt justified in regarding as the cause of the disease. If they are correct in this assumption, we may perhaps look on the Flexner and Noguchi organism as a form which this coccus takes when grown anaerobically. One of the most interesting statements made by Rosenow is that regarding his success in isolating this organism from the tonsils of patients suffering from the disease, an observation which might have an important bearing upon the treatment and epidemiology of poliomyelitis. If, as these authors believe, the tonsil is the focus in which the streptococcus so develops as to acquire its elective affinity for the central nervous system, then the removal of the tonsils should have a marked influence upon the incidence of the disease. It is doubtful if any physician at the present time would have the temerity to advocate wholesale removal of the tonsils of children, but if Rosenow's hypothesis is established there will doubtless be a tremendous sacrifice of the tonsils of the young and helpless when another epidemic appears. The removal of the tonsils even during the course of the disease is said to have had a favorable influence upon it in a few cases.

The work is, of course, in the line of confirmation of Rosenow's theories concerning the streptococcus, but the problem is far too large for it to be worked out in so short a period of time; one way is merely pointed out, and there will probably be no lack of workers to follow it. The objections to this theory that will occur to every one are innumerable, and it will be necessary to reconcile it with many of the apparent facts of quarantine, immunity, curative sera, and the like; and then there is the work done at the Johns Hopkins seeming to point to an intestinal localization, though of that we know little beyond what has appeared in newspaper reports. Nevertheless, the investigation by Rosenow and his associates will stand as a good piece of work, and even if, eventually, the whole theory is disproved, the observations are there, and only the interpretation can change.

THE IRRITABLE HEART OF SOLDIERS.

RECENTLY a good deal has been written concerning the soldier's heart. Sir James Mackenzie has expressed his views on the subject, while Sir James Barr has given his somewhat original ideas in a paper published in *American Medicine* for September, 1916. In the September issue of the *Canadian Medical Association Journal* Dr. Robert Dawson Rudolf, Professor of Therapeutics in the University of Toronto and Lieut.-Colonel Canadian Expeditionary Force has contributed a paper dealing with the question. He does not agree wiith Barr as to the causation of the so-called soldier's heart but is in more or less complete agreement with Mackenzie with regard to the nature of the condition. Rudolf points out that soldier's heart, as witnessed at the French front, can hardly be due to strain of the heart muscle to which it has been largely attributed for the reason that trench warfare does not give rise to strain sufficient to damage a previously healthy heart muscle. On the other hand the strain to which the nerves are subjected by the mode of warfare in France no doubt has much influence. All kinds of functional nerve conditions are encountered, including nervous instabilities of the circulation. The heart and vessels are very largely under the control of the nervous system and the rate of the pulse is perhaps a better index of the state of this system than anything else. Moreover, as Rudolf points out, when the whole nervous system is under such tension it will yield, if at all, at its weakest point, and the weakest point varies in different individuals. If a person's circulation is his weakest point, then that is where it is most likely to give way. Rudolf's conclusions are as fol-

lows: (1) The condition called "soldier's heart" is not an entity but includes merely the worst examples of a circulatory instability that grades up from the nearly normal to a degree so great that it may completely incapacitate the patient. (2) The circulatory instability has often been there before and is merely brought into prominence or exaggerated by the unusual physical and mental surroundings of a soldier's life. The very same condition occurs, only more rarely, in civil life. (3) In many cases the condition appears to be caused or precipitated by infection with consequent toxemia, also by nerve shock or strain, but in many instances no such clear origin can be traced. (4) The condition appears to be essentially one of neurasthenia in which the circulatory apparatus happens to show the most symptoms. (5) The best test of the degree of the condition is to take the history in conjunction with the pulse rate when the patient is standing. (6) The treatment is not that of ordinary heart disease, but should be directed in every possible way toward increasing the general tone, including the mental tone of the sufferer. (7) The patient should not be told, or allowed by our bearing towards him to think that he has "heart disease" as such is not strictly the case, and such a belief does much harm. (8) The progress in well-marked cases must be guarded, but the great majority of patients bad enough to be invalided home will probably not be fit for "full duty" for a long time, but will eventually be quite capable of doing light duty. (9) The ultimate fate of the bad cases (after years) remains to be investigated.

Sir James Barr, to whose views reference has been made, attributes the condition simply to hyperthyroidism, basing his conclusions on the study of soldiers back from the front. The treatment, therefore recommended by Barr is directed to the condition of the thyroid gland and he claims to have received excellent results from it. The weight of evidence as to the causation of "soldier's heart" is, however, with Sir James Mackenzie and those who agree with him, albeit Sir James Barr has made out a plausible case. It is a question of very considerable importance, as the irritable heart occurs more or less frequently in civil life. It is therefore to be hoped that the problem will be solved in the near future.

SHALL WE PUNISH MANIACS?

A SITUATION which constantly confronts the physician in charge of the insane, and which the general practitioner occasionally encounters, is the problem of the excited patient who, left to himself, would tear up everything about him, including his own clothes, soil his surroundings, injure himself and assault others. To his exasperated guardian he often seems to be actuated by a malicious spirit, and this impression is heightened by his conversation, which is apt to be abusive and allusive to the highest degree, enumerating his physician's failings accurately, and indulging in the grossest and most vulgar personalities. It is but human to want to tie up a patient who has just slapped one in the face, and it is easy to be convinced that such a patient's reasoning powers, being in abeyance, he should be treated as a child.

Let us not delude ourselves with the idea that we are engaged in any sort of a therapeutic measure when we have to resort to tying down such a patient. In the reports of a hospital for the insane we sometimes find a record of so many "dry-packs" given in the course of a year. The term "dry-pack" is a euphemism given to the process of tying an excited patient hand and foot for a given time. Hot and cold packs, either of the sheet or blanket variety, have, of course, their proper therapeutic indications, and the hot or cold water acts as a sedative or a stimulant, depending on various things. The "dry-pack" can, by no stretch of the imagination, be conceived to have any therapeutic value. The officers of these same hospitals boast that no patient is "restrained" in their institutions, and salve their consciences by calling their cases—really the most severe form of restraint—"dry-packs." Any one can get an idea of how one feels in a "dry-pack" by reading the scenes in Charles Reade's "It's Never Too Late to Mend," where the prison chaplain tests the form of punishment of lacing a prisoner in a tightly-strapped jacket; or to allude to actual experiences he can read the description by Clifford W. Beers in "A Mind That Found Itself," of the night he spent in a straitjacket.

We are getting gradually away from the old idea of treating the mentally disordered as if they were criminals. We no longer think it necessary to put chains on maniacs or even to stupefy them with drugs. Psychotherapy between attacks and hydrotherapy during the attacks are the methods of choice. Of all forms of hydrotherapy for excited cases, the continuous bath is the best, and it has the great merit that it can be administered, in a somewhat modified form perhaps, in nearly every private home. It is interesting as illustrative of the changed attitude towards mental cases that at first it was thought necessary to tie the patient in a continuous bath, with the result that finding himself restricted in his movements, he struggled to be free. Now he is merely put in the bath and watched. He may at first get out and run about the room, but he is soon chilly enough to be glad to step back into the warm tub.

We should conclude, therefore, that everything in the way of disciplinary measures for mental cases is absolutely contradicted both for the sake of justice and for therapeutic reasons. The maniac should be treated, not punished. If it is impossible for any reason to give him adequate hydrotherapeutic treatment, or to watch him constantly so as to prevent him doing damage to life or property, and it is found necessary to restrain him in some way, let the physician at least be honest enough to acknowledge that it has been found necessary to restrain his patient, and not call his bonds a "dry-pack."

FERRAN ON THE BACTERIOLOGY OF TUBERCULOSIS.

As is generally known, Koch's bacillus does not explain all the phenomena of tuberculosis, and especially does it fall short in connection with the problems of acquired immunization. Some authorities

go so far as to state that the acid-fast bacillus of Koch is wholly devoid of either immunizing or curative powers. If there were not some natural immunizing forces in the body tuberculosis would in a short time destroy the race. Koch's bacillus cannot confer such protection. Ferran, the Spanish bacteriologist, insists that when tuberculosis arises *de novo* in the body, it is not caused by Koch's bacillus as such, although the power of the latter to cause inoculation tuberculosis is not called into question. According to Ferran, Koch's bacillus makes up but a small fraction of the complete biology of spontaneous tuberculosis, being merely the last step. Ferran says that in human beings conjugal infection but rarely occurs—the incidence varies from 7 to 22 per cent. according to the material—and he does not understand how any spouse could escape infection if Koch's bacillus was the sole or even the chief agent of transmission.

Ferran holds that Koch's bacillus is naturally a saprophyte. He finds five varieties of bacteria present in tuberculosis, one of these representing the classical acid-fast bacillus of Koch. Literally it is the fourth term of an ascending mutation, due to adaptative evolution. A further form is that derived artificially from the tubercle bacillus. The Koch organism is by no means the same thing as the virus of tuberculosis. The artificial form is regressive, just as the three ascending forms are progressive, Koch's bacillus standing at the apex. The natural forms cause spontaneous tuberculosis but are not infectious from man to man. They are ubiquitous, in the air, soil, and water. If by any chance they enter the blood they give rise to a form of septicemia. If they gain access to the tissues, there is no immediate reaction, but instead a process of adaptation on the part of both bacterium and host, the latter obtaining a general immunization from the formation of antibodies in the blood, while the former tends to pass through mutations until Koch's bacillus is formed. If the latter stage is reached there has been no immunization—the individual is tuberculous; but in the majority of cases this is a local process admitting of spontaneous arrest, the subject is affected, but not infected with the disease.

Ferran's teachings apply to bacteriology in general and go far to fill a number of defects in present day teaching. According to Persano (*Rivista critica di clinica medica*), these views have excited much controversy. The opposition is based partly on the claims that vaccines and sera produced under Ferran's teachings have not yet led to practical results. Ferran's rejoinder to his critics is that his methods are in the experimental stage, but show encouraging results. Evidently several years must elapse before a final judgment regarding these claims can be formed.

Simulation of Sciatica.

Sciatica, having no objective characteristics, is an affection which invites simulation. Patients who have recovered from other affections in hospitals have obtained an extension of their sojourn by this means. Lasègue's sign—accentuation of pain as a result of traction on the limb—is of great value in exposing simulation, but the malingerer soon learns to show pain under this maneuver and to imitate the defense exerted by the true subject of the disease. In *La Riforma Medica*, for July 10, Neri suggests a substitute procedure as follows: The subject is asked to stand and make various indifferent movements, such as elevation of an arm, bending forward, folding the arms, etc. If he has sciatica there will be some embarrassment in flexing the trunk on the lower extremities, flexion is more pronounced on the healthy side, and there is a slight rotation toward the affected side. Or the affected member may be flexed on the body, in which case the heel will be elevated, while the patient, feeling a severe pain at the sciatic foramen supports himself on the sound limb. In the simulator these flexions are produced without reactions, or defence movements, which are wholly instinctive. On the cadaver the author learned that the flexions cause stretching of the sciatic nerve. Vigorous active and passive flexions of the head on the trunk also cause pain in sciatic nerve of a sciatic victim, this being felt at the sciatic foramen. If the patient is supine, flexion of the head may cause a slight flexion of the hip upon the pelvis and of the leg on the thigh. This defence reaction is sometimes accompanied by clonus. This behavior has been explained by the possibility of a drawing upward of the medulla oblongata, corresponding to the flexion of the head, with a resulting traction upon the nerve radicles. It is evidently, however, not pathognomonic for sciatica.

Hepatic Prophylaxis.

The various manifestations comprised under the term hepatic insufficiency have been freely discussed in recent years, and in the more severe types we see urobilinuria, alimentary glycosuria, aminoaciduria, and acidosis. There is a form of true diabetes due to this causation, and functional insufficiency is a forerunner of cirrhosis of the liver, as shown by the urobilinuria which precedes that affection. Given a condition of hypohepatism (to paraphrase the terminology of thyroid pathology) how is it to be antagonized? Regnier (*Gazette Médicale de Paris*) states that proper diet is the first requirement. The subject cannot digest fats and articles containing fats, and has grayish stools, diarrhea and constipation alternating. He is drowsy by day and wakeful at night. He is intolerant to alcohol and tobacco, has no desire to work, is melancholic. In addition to fats, he must eschew wine, spices, sauces, excess of meat, fresh bread, pastry, yolk of eggs, shell fish, and an entire series of dishes which might disagree. No chemicals should be given. The author advocates lactic acid ferments, which may be combined with selected yeasts. To stimulate the hepatic cells he counsels organotherapy and gives hepatic and splenic extracts and bile salts. The latter are especially valuable and may be all that is necessary. He has great faith in hepatic extract, which has a beneficent action on the blood in increasing its coagulability, and he regards it as the logical remedy in impending cirrhosis. According to him, older as well as more modern clinicians (Semmola, Joffroy, Millard, *et al.*) have made this use of organotherapy. The urine which characterizes hypohepatism is said to return to the normal under this treatment. Cirrhosis, whatever form it may take, is always preceded by a certain degree of hepatic insufficiency.

News of the Week

Poliomyelitis Epidemic.—During the week ending October 21 there were reported in New York 41 new cases of poliomyelitis, making a total to that date of 9,243 cases, of which 2,379 have been fatal. Cases of the disease have also been reported from several places in the State. At Ithaca, eleven students at the University have been quarantined because of the occurrence of a case of the disease in the house in which they roomed. Other cases have been reported in schools and colleges in New York, Connecticut, and New Jersey, but no serious outbreak has occurred. In Westmount, near Montreal, two cases of poliomyelitis developed shortly after the holding of a dog show, and it has been suggested that the disease was introduced by dogs from New York exhibited at that time.

Need for School Physicians.—The New York Bureau of Welfare of School Children has recently sent to the Board of Estimate of this city a memorandum urging that provision be made for the appointment of additional inspectors, physicians, and nurses in the public schools. It is stated that during the last school term each school physician had the care of 9,200 pupils, and each nurse of 4,800. It is possible, under the present conditions, to examine each child only once in three years, whereas an annual examination is essential.

Fire in Hospital.—A blaze in a bathroom and clothes hamper, in the women's ward of the Lutheran Hospital, Brooklyn, on October 21, caused some alarm among the inmates, but was extinguished before serious damage had been done.

Balkan Relief Fund.—For the relief of the people of Albania, who, their land devastated by the opposing armies, are literally starving to death, an attempt is now being made to raise funds. Appeal is made for contributions in any amount, and these may be sent to the Balkan Relief Fund, 70 Fifth Avenue, New York.

Gifts to Charities.—By the will of the late Dr. James Y. Shearer of Sinking Springs, Pa., the sum of $60,000 is bequeathed, following the death of the wife and daughter of the testator, to Jefferson Medical College, Philadelphia, to be used for the endowment of a chair of bacteriology.

To Dedicate Hospital.—The new Lutheran Hospital at the northeast corner of Convent Avenue and 144th Street, New York, will be dedicated on October 29, and opened to the public on the following day. The buildings were made possible largely by the generosity of Dr. Inslee H. Berry, one of the founders of the hospital, whose entire residuary estate, on his death in 1912, passed to the institution. With this, and further gifts received since that time, the directors have erected a hospital and provided an equipment complete in every detail.

Personals.—Dr. William Seaman Bainbridge of this city was elected an honorary member of the Vermont State Medical Society at its annual meeting recently held in St. Johnsbury, and of the Society of Pennsylvania Railroad Surgeons at the annual meeting in Philadelphia on Friday of last week. He delivered the oration at the meeting of the Pennsylvania Surgeons.

Dr. H. H. M. Lyle of New York spoke before the Waterbury Medical Society, Waterbury, Conn, on October 9, describing the results of the Carrel method of sterilization of wounds as he had observed them during his service in France, and as detailed in the report of the Surgical Section of the New York Academy of Medicine, published in another column of this issue.

Dr. David S. Booth has undertaken the editorial management of the *Alienist and Neurologist* of St. Louis, upon the death of its editor, Dr. C. H. Hughes, pending the appointment of a permanent editor.

The Diagnosis of Diphtheria.—Dr. D. L. Gaillard of Greenville, Tex., writes that for years he has depended upon swabbing the suspected tonsil with solutions of the perchloride of iron as a diagnostic help in diphtheria. In follicular tonsillitis the deposit is broken up, in diphtheria the membrane is stained only. Dr. Gaillard asks that others try this method and report the results.

Removals.—Dr. William A. Downes has removed his office to 424 Park Avenue.

Dr. Fellowes Davis, Jr., has also removed to 424 Park Avenue.

Dr. Edward Lindeman announces the removal of his office to 565 Park Avenue.

Society Elections.—Medical Association of the Southwest: Annual meeting at Fort Smith, Ark., on October 2 to 4. The following officers were elected: *President*, Dr. Everett S. Lain, Oklahoma, Okla.; *Vice-presidents*, Dr. H. L. Snyder, Winfield, Kan.; Dr. J. H. Thompson, Kansas City, Mo.; Dr. M. M. Smith, Dallas, Tex.; and Dr. Charles S. Holt, Fort Smith, Ark.; *Secretary-Treasurer*, Dr. Fred H. Clark, El Reno, Okla. The next meeting will be held in Kansas City, Mo.

Fairfield County (Conn.) Medical Society: Annual meeting at Noroton on October 10. Officers elected: *President*, Dr. Frank H. Barnes, Stamford; *Vice-president*, Dr. Frank M. Tukey, Bridgeport; *Secretary*, Dr. Eli B. Ives, Bridgeport; *Treasurer*, Dr. Henry B. Lambert, Bridgeport.

Vermont Homeopathic Medical Society: Annual meeting at Montpelier on October 11. Officers elected: *President*, Dr. E. B. Clift, Fair Haven; *Vice-president*, Dr. W. G. Hodsdon, Rutland; *Secretary*, Dr. George I. Forbes, Burlington; *Treasurer*, Dr. F. E. Steele, Montpelier.

School of Chiropody.—The faculty of the School of Chiropody of New York has recently been increased by the addition of the following: Dr. Edwin C. Adams, professor of surgery; Dr. Paul Luttinger, director of laboratories; Dr. Joseph Mark, adjunct professor of physiology; Dr. E. C. Rice, associate professor of clinical chiropody; Dr. Harry E. Mereness, Jr., lecturer in pathology; Dr. Carl C. Franken, lecturer in bacteriology; Dr. S. S. Markell, lecturer in surgery. The student body of the school now numbers over one hundred.

Surgery in Moving Pictures.—Vivid pictures of the wonderful surgery done by Dr. Alexis Carrel and others on the wounded soldiers in French hospitals have recently been made with a cinema camera and brought to this country by the Clinical Film Company. The picture will be shown before medical societies, medical students, etc., and, judging from the reported effects of a private view given to representatives of some of the New York newspapers recently, it is hardly probable that they will appeal to any but technical audiences.

The Late Dr. Marple.—The Board of Surgeons of the New York Eye and Ear Infirmary record with deep sorrow and sincere regret the death of the late Dr. Wilbur Boileau Marple, who died suddenly at Kennebunkport, Me., September 30, 1916. Dr. Marple had been connected with the infirmary for

twenty-five years, first as assistant surgeon, and from 1901 to the time of his death as attending surgeon. He was also for a number of years one of the representatives of the Board of Surgeons on the Board of Directors.

The death of Dr. Marple has removed from among us a distinguished ophthalmologist, admired colleague, wise counsellor, and honored friend. His loss is greatly deplored by all of us. The Board of Surgeons desire to express their appreciation of his high professional attainments, and extend to his bereaved family their profound sympathy. (Signed) John E. Weeks, M. D., Edward B. Dench, M. D., W. E. Lambert, M. D.

Obituary Notes.—Dr. James Albert Cowan of New York, a graduate of the College of Physicians and Surgeons, New York, in 1904, died at his home, from apoplexy, on October 15, aged 43 years.

Dr. Oliver L. Hudson of Princeton, Ind., died at his home on September 22 after an illness of several weeks, aged 86 years.

Dr. A. B. Daniel of Claxton, Ga., a graduate of Jefferson Medical College, Philadelphia, in 1857, died at his home after a long illness, on September 30, aged 82 years.

Dr. Lawrence Yancey King of Florence, S. C., a graduate of Louisville Medical College in 1891, died suddenly on September 30, at Richmond, Va. Dr. King was a member of the Kentucky State Medical Association and the Florence County Medical Society.

Dr. Henry J. McKenna of Long Island City, N. Y., a graduate of the University and Bellevue Hospital Medical College, New York, in 1901, a member of the Medical Society of the State of New York, the Queens County Medical Society, and the Associated Physicians of Long Island, and visiting surgeon to St. John's and the Long Island College Hospitals, died in New York on October 17, aged 37 years.

Dr. Nathaniel Matson of Brooklyn, N. Y., a graduate of the New York University Medical College, New York, in 1864, and a member of the Medical Society of the State of New York, the Kings County Medical Society, the Associated Physicians of Long Island, the Brooklyn Medical Society, and the Brooklyn Pathological Society, died at his home on October 14, aged 77 years.

Dr. David F. Lincoln of Boston, a graduate of the Medical School of Harvard University in 1864, died at his home on October 17, aged 75 years.

Dr. William Preston Miller of Hagerstown, Md., a graduate of the University of Pennsylvania, School of Medicine, Philadelphia, in 1894, and a member of the American Medical Association, the Medical and Chirurgical Faculty of Maryland, and the Washington County Medical Society, died at his home, from pneumonia, on October 5, aged 46 years.

Dr. William Stiles, Jr., of Philadelphia, a graduate of the Hahnemann Medical College and Hospital of Philadelphia, in 1875, died at his home on October 7, aged 74 years.

Dr. John Savile Lees of Bridgeport, Pa., a graduate of the University of Pennsylvania, School of Medicine, Philadelphia, in 1863, died at his home on October 9, aged 74 years.

Dr. William Peter Knight of Luverne, Ala., a graduate of the Southern Medical College, Atlanta, Ga., in 1892, and a member of the Medical Association of the State of Alabama and the Crenshaw County Medical Society, died suddenly on October 4.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

INJURIES TO GREAT CERVICAL VESSELS—EMBOLISM—BLOOD PRESSURE — CEREBRAL ANEMIA — SCARLET FEVER—TYPHOID FEVER—LONDON'S MEDICAL OFFICER OF HEALTH.

London, September 30, 1916.

Sir G. H. Makins has published a group of cases illustrating some of the effects of injuries to the great vessels in the neck. Cerebral embolism is somewhat frequently the consequence of such injuries and the thrombi may be entirely independent of septic infection. But if the vessel lie exposed in an infected wound the thrombus is likely to disintegrate and septic emboli may be set free, or secondary hemorrhage may occur when the damaged arterial wall is exposed to the full force of the blood pressure. Such cases show that embolic obstruction of even minor cerebral vessels may have more serious effects than the blocking of vessels supplying small areas of a limb where anastomosis is not much interfered with. Cerebral disturbance due to such wounds is occasionally met with in civil practice; in fact, more often than was supposed before military practice demonstrated its frequency. The cases are important, the prognosis unfavorable, and the clinical symptoms so complicated as to obscure the diagnosis and history. Abolition of pulse, superficial or temporal, is evidence of obstruction or complete obliteration of the arterial lumen. But although a corroborative factor, this is by no means a necessary sign for diagnosing arterial thrombus, a lateral mural thrombus projecting into the lumen of a vessel may grow and quite obstruct the vessel or it may get detached and be the obstruction; it may as such prove more dangerous than greater damage causing more rapid and complete formation of the occluding thrombus with a firmer attachment to the whole circumference of the vessel, giving it greater resisting ability to the blood pressure. In these cases this pressure is a rising one as the shock of the injury passes off. Arterial lesion is the more probable when both apertures—entry and exit—are present. So it is when a retained missile can be detected by x-rays. The coexistence of signs of injury in contiguous structures is a further aid to diagnosis, particularly injury to the sympathetic chain.

The striking difference of these cases from those dependent on sudden cerebral anemia, such as follows ligature of the carotid, is mentioned. Primary or secondary hemorrhage and complete hemiplegia leading in many cases to a fatal issue in 24 to 36 hours. In the emboli cases the paresis is more slowly developed. As to treatment, rest appears to be the only hope, and that but a feeble one.

The annual report of London's medical officer of health is on the usual lines and one need not say that the statistics it contains are as full as ever and offer a basis for many investigations. Many of the charts are so good that they seem able to convey their message almost independently of the text. Those whose work has any relation to its contents will need no reference to it—they will already have been considering it. There was a slight decline in the estimated population for 1914, attributed by many to the difficulty of poor persons with families obtaining the accommodation they require within the county who are therefore obliged

to reside at some distance. The expectation of life in these last returns again shows an increase, and that for both sexes and for all periods of life. The marriage rate is higher than in any year since 1874. But the birth rate has continued its fall, and is now 24.3 per 1,000. It was 25 for the period 1909-13. The death rate is again very low—14.4, as against 13.7—for the whole of England and Wales. The highest rate is in Shoreditch; the lowest in Lewisham. The first quarter of the year has the highest incidence; the second quarter the lowest.

The infant mortality again has a lower rate—104 per 1,000 births, against 107 in the preceding five years. Some cases of smallpox were found at the port and measures promptly enforced to prevent it spreading were successful. A double notification of measles and smallpox occurred in some districts, the schools as well as the sanitary authorities also reporting a similar return of whooping-cough. Scarlet fever had a slight increase in the rate. The wave curve of this disease corresponds with one showing the prevalence of fleas; also with one in inverse relation to rainfall. Typhoid broke out at the turn of the year 1913-14 and was traced to a particular establishment, and in that to the kitchen. There were 789 cases, and in 400 the source of infection traced. Trash sold in the streets, fish and shellfish, are considered to be sources of danger in London. But the improvements in sanitation have done much to restrict the growth of the typhoid toxin in the capital, and the greatest danger is from cases imported from polluted foreshores and distant estuarial waters.

8. The Value of a Program of Work for Anti-Tuberculosis Societies. Mrs. W. H. Lothrop.
9. Report of the Secretary of the Massachusetts Tuberculosis League. Seymour H. Stone.

2. The Massachusetts Tuberculosis League.—Remarks by the President.—Vincent Y. Bowditch, in his address before the Massachusetts Tuberculosis League on the occasion of its second annual meeting, reviewed the purposes for which the League was established. These are to keep watch upon the work which is being done throughout the State, to note and encourage those communities where work is being actively done, to stimulate to action those in which there possibly has been, and may still be, indifference as to the importance of all anti-tuberculosis work. He emphasizes three points as most important in the anti-tuberculosis campaign: First, there is need of a more rigid enforcement of the present law requiring all cases of tuberculosis to be reported by the attending physician to the proper authorities. Such an enforcement in the present state of public opinion may at times be embarrassing to the physician in attendance, but at the same time the public must be taught that registration, not necessarily meaning discomfort to the patient or friends, is absolutely necessary if the disease is to be brought under control in the future. Second, a constant endeavor should be made to induce proprietors of mills, factories, and shops to watch the health of their employees more carefully and attend to the hygienic surroundings of their workers. Much has been done in this direction but there is still vast room for improvement in the future. Third, there is need for the establishment of open air schools not only for those already ill, but for those not afflicted but who need to be fortified against disease. No one familiar with the work of the open-air schools can fail to be impressed by what can be done by such measures to restore health to tuberculous children. Similar methods could be adopted by all schools with infinite benefit to preventive medicine.

6. Tuberculosis in Rural Communities.—Vanderpoel Adriance summarizes the situation in respect to rural tuberculosis by stating that rural communities are very ignorant of the prevalence of tuberculosis and have been neglected in the anti-tuberculosis campaign. The formation of anti-tuberculosis leagues should be encouraged in such communities. The State Board of Health should be encouraged to make a thorough survey of the prevalence of the disease and should enforce the law which demands instruction about tuberculosis in the public schools. The education of the public school children on the subject of tuberculosis is of prime importance, not only from the standpoint of the individual child but because in it lies the main hope of this campaign, since the children of today will be the workers of the next generation. Instruction in regard to bovine tuberculosis is especially needed. Bovine tuberculosis is commonly conveyed through milk and is a menace, particularly to children under five years of age. There should be a state law compelling the pasteurization of all milk.

7. Some Problems of the Massachusetts Hospitals for Consumptives.—Arthur K. Stone mentions as among the problems confronting the trustees of hospitals, lack of cooperation on the part of communities and local health boards and the difficulties of administration. One of the most difficult problems concerns a class of patients who, after a period of progress, seem to come to a standstill, or the progress is very slow indeed. Some, though the active progress of the disease is arrested, show that they can never become self-supporting, active citizens again. They can live, and happily, under the protecting walls of an institution. Some of these persistently have bacilli and some never have bacilli or only at long intervals. The question comes up as to what shall be the attitude of the State to these persons. In the course of years groups of such patients tend to collect at various institutions and the question is asked, "What is to be done with them?" To this group must be added a group of patients where, in spite of marked symptoms and signs in the lungs, there is nevertheless grave doubt whether the process is that of real tuberculosis, or rather of so-called chronic bronchitis or bronchiectasis. These people are sick and suffering, but they are not, so far as is known, dangerous to the public health. It is desirable to know to what extent the State should make provision for their care. A difficult therapeutic question to be solved is how, after the period of rest has passed and the patient has returned to a normal temperature, and bacilli have disappeared from the sputum, shall he obtain the graduated work necessary to put him in the best possible condition to enable him to return home capable of being a productive citizen?

2. Epidemic Poliomyelitis. — W. Sohier Bryan discusses the nasopharyngeal aspects of poliomyelitis. He believes that the experimental work of the past six years has given abundant proof that the virus or microorganism of poliomyelitis occurs first on the mucous membrane of the nasopharynx and is given to other victims through the excretions of the nose and throat. He points out that abortive cases and carriers are computed to be four or five times as many as are patients with distinct paralytic symptoms. The infection of the mucous membrane of the nasopharynx is so general and so far spread that the quarantine net cannot catch all the people carrying the infection. In view of the problems presented he suggests the management of the nose and throat with the view of making the pharynx a poor culture surface for the virus. The care of the nasopharynx should be made a routine matter; the public should attend to the conditions of the nose and throat in the same manner that it attends to the care of the teeth. Health authorities and family physicians should urge regular examination of the tonsils, adenoid and nasal passages for the treatment of infected mucous membrane. The key to the prevention of epidemic lies in such care. Those coming into contact with cases of poliomyelitis should have special nasopharyngeal treatment, consisting of sprays, applications through the nose, and the insufflation of powders through the nose. Since no specific treatment is known for poliomyelitis it is necessary to use those agents which have proven advantageous in nasopharyngeal infection from other organisms, such as silver salts, iron salts, phenol, corrosive sublimate, essential oils, iodine solutions, kaolin, calomel, quinine sulphate, charcoal, etc. The following is a description of the technique of one of the methods of treatment suitable for prophylaxis and for the purpose of lessening the dose after the infection: Spray the nose with a solution of 1 per cent. cocaine with one in 8,000 adrenalin to shrink the turbinates and slightly deaden sensibility. With a small cotton carrier apply hydrogen peroxide through the inferior meatus of the nose to the back wall. If there is much effervescence of the hydrogen peroxide, make several applications until effervescence has subsided and wipe the foam from the mucous membrane. If incidentally in this application the adenoid tissue appears to be very thick apply nitrate of silver (10 per cent., children; 25 per cent., adults) with a small dry applicator to the region of the adenoid and the pharyngeal pituitary, being careful not to use enough to permit its running down into the pharynx. If the adenoid tissue feels smooth and thin use a saturated aqueous solution of ferrin alum. For prophylaxis repeat the treatment after four days.

3. Intracranial Murmur of Long Duration and Spontaneous Cessation.—Frank K. Hallock relates the history of a patient, forty years of age, who from her earliest recollection had a pulsating sound in the head, variously described as "pounding," "whistling," "steam escaping," etc. When thirty-eight years of age, after an ocean voyage, she lost this sound, which had not returned save for a few seconds during a delayed and disturbed menstrual period. The systolic bruit could be heard by the stethescope at all points on the cranium, but was most marked in the left occipital and postauricular regions. On the left side of the head the sound was loud enough to be heard with the naked ear held close but not touching the scalp. Its character objectively was that of a steady, pulsating, whirring, rushing sound, synchronous with the pulse. Ordinary exercise and body movements did not modify the sound to any extent. Turning the head sharply to the right stopped the murmur both objectively and subjectively, while rotating the head to the left or flexing it downward did not interfere with the sound. In discussing the possible diagnosis in this case the writer assumes that this systolic bruit was due to a structural arterial abnormality existing from childhood. He says that this murmur would ordinarily be diagnosed as aneurysmal or its equivalent, but in addition to a constricted, dilated, or sacculated portion of artery, one could also picture the possibility of a sharply tortuous, angulated, or kinked section, either free or in relation to some bony or soft growth or projection. It might be that in these later years with a more equalized and better balanced vascular system there was a somewhat lessened flow of blood in the cerebral vessels and a slight diminution of the fluid volume within the cranium. This would favor the cessation of the murmur.

6. Extrauterine Gestation. — Earl P. Lothrop discusses the diagnosis and treatment of extrauterine gestation and reports five cases in which the diagnosis was made before operation. He says that when a correct diagnosis was made before operation the operator should thank his intuition rather than his judgment. The histories of his cases show that most cases present suggestive symptoms at the time of rupture. There is usually sudden pain followed by flowing, and a feeling of faintness or collapse may follow these symptoms. After rupture the history of repeated attacks, together with the finding of a pelvic tumor, may guide one correctly. In all cases the possibility of gonorrheal salpingitis should be carefully considered. An analysis of the writer's series of 83 cases shows that their ages ranged from 21 to 41 years, 54 occurring between the ages of 21 and 36 years, 19 between the ages of 36 and 41 years, and in 10 cases the age was not correctly given. The gestation was going on in the right tube in 43 cases and in the left in 40. The number of tubal abortions was 15; unruptured, 5. Of the ruptures two were interstitial. Fifty-nine occurred in the middle of the tube; two at the fimbriated end. In this series of 83 cases there was only one death from shock a few hours after the operation. In 15 cases the other tube was diseased and in 21 there was a chronic appendicitis. Three cases had been operated on for tubal gestation on the opposite side. The writer thinks conservative treatment in cases with mild symptoms and slow bleeding with the development of hematocele, when seen late, is permissible, but that such cases should be kept under observation and operation performed later if there is a recurrence of hemorrhage. He outlines the usual operative procedures and concludes that every case of supposed pregnancy in which sudden pain develops, flowing or shock should be considered extrauterine until proven otherwise.

7. Status Lymphaticus.—William Ledlie Culbert reports two cases of what for the want of a more definite term is usually called status lymphaticus. These cases serve to draw attention to the importance of a thorough physical examination of all children who present themselves for operation, especially those for removal of tonsils and adenoids. When a child shows any deviation from normal we should look all over the body for enlarged glands, bone deformities characteristic of rachitis, and areas of sternal dullness. Pribram of Prag draws special attention to enlarged papillæ at the base of the tongue and an omega shaped epiglottis as significant of this condition. If any stigmata are present suggestive of an enlarged thymus, operation

should be refused, or at least deferred until a full laboratory investigation can be made, including skiagraphs.

8. **Cystoscopic Rectovesical Transillumination.**—P. S. Pelouse states that the digital examination of subvesical structures per rectum is at best uncertain and that he has made an application of the old method of transillumination to these structures. He inserts the cystoscope into the bladder, dilates the viscus with water, introduces an electric bulb into the rectum, and turns out the cystoscopic light; this makes it possible to transilluminate the intervening structures. This can be done so thoroughly that the tiny blood vessels at the base of the bladder are distinctly seen, changes in tissue thickness and density can be accurately determined, and the ureter followed for a short distance. The essayist has had made a curved shaft for carrying a large transillumination lamp which makes it possible to bring a larger field under observation. The value of this procedure is in the determination of infiltrations of tissues from vesical, prostatic, or rectal growths, and the diagnosis of stones in the lower end of the ureter.

9. **Obstetrical Abdominal Hysterectomy.**—Alfred M. Hellman relates his experience with twelve cases of abdominal cesarean section. He gives thirteen indications for cesarean section and states that the abdominal operation is preferable to the vaginal, because it takes less time, assures greater cleanliness, the abdominal incision is wholly under the control of the operator, the patient can be sterilized if needed, and tumors can be removed By the abdominal operation one is more likely to get a viable fetus. Rupture of the uterus is more likely to occur if a low incision is used than if a high one. The bladder and ureters will not be injured by a high incision. The adbominal cesarean section also returns the parts much more nearly as they were before than does the vaginal incision. The convalescence is less painful and more likely to be smooth. In concluding, Dr. Hellman says it is time that the general practitioner learned that there is a safe method of delivery in complicated but uninfected cases, one that is free from the multilating effects of forceps, version, and the like, and it is time that this same truth is brought home to the laity.

4. **Anesthesia in Human Beings by Intravenous Injection of Magnesium Sulphate.**—Charles H. Peck and Samuel J. Meltzer state that in this preliminary report they wish to relate briefly the course of anesthesia in three operations performed on human beings exclusively under the influence of intravenous injection of magnesium sulphate. In summary they state that the observations made in these cases prove conclusively that the state of anesthesia which is produced by injection of magnesium sulphate is actually anesthesia, that is, that in this state sensation as well as consciousness are temporarily more or less completely abolished. This central effect may or may not be accompanied by a pronounced paralysis of the endings of the motor nerves of a great part of all skeletal muscles. Evidently the central effect, especially the effect on the sensation of pain and on consciousness, can be obtained with a smaller dose of the magnesium salt than that which is required for a paralysis of the motor nerve endings. The central effect also appears to set in sooner than the peripheral one. The employment of intravenous injection of magnesium salt as an anesthetic may prove to be indeed a practicable and advantageous method, because, in the first place, it may cause simultaneously a moderate degree of relaxation of the muscular mechanism, and, secondly, because the untoward effects can be rapidly reversed by a careful administration of a solution of calcium chloride. This method, however, before it can be made practically serviceable, would require a good deal of careful study. They, therefore, at least for the present, abstain from a discussion of the possibility of the practical applicability of this method.

8. **Nail Extension in Fractures of the Lower Extremity.**—John C. A. Gerster claims the following advantages for this method of treating fractures of the lower extremity: (1) It is a safe measure provided the proper technique is employed. (2) Because of its small site of attachment, it is of great value in recent simple fractures with extensive abrasions, in recent compound fractures with much destruction of soft parts, and in multiple fractures of the same limb. (3) Because of its efficient traction, in conjunction with osteotomy, it is the only method whereby the shortening present in certain old malunions can be safely overcome even months after the original fracture. (4) In relation to open operative reduction, it may be stated that in certain cases nail extension will obviate the necessity for operative intervention, and in other cases it can be employed to prevent shortening until the suitable time for plating has arrived.

9. **Nails and Screws Through Joint Surfaces, in Autografts, and in Fractures into Joints.**—Arthur T. Mann writes that his experience warrants the conclusions that: (1) The autografts unite with a line of callus as fine as those of simple fractures, with a free joint, and without adhesions. (2) The autografts seem to live, but in reality the bone trabeculæ are gradually replaced by microscopic bone growing inward from the vascular spaces between them, while the cartilage continues to live and to a limited extent aids in the formation of the new bone adjacent to it. (3) The main replacement of the bone in the trabeculæ seems to take place directly from bone cells without the preliminary formation of cartilage, and the dead portions of the trabeculæ seem to be absorbed in a line immediately adjacent to the new growing bone without the inter-

vention of special osteoclasts. (4) Condyles detached from all tissue save the crucial ligament unite like free autografts. (5) Condyles, attached more or less to other tissues as well, continue to live throughout, or nearly so. (6) Nails and screws are tolerated in the human being as well as in the experimental cases, and with surprisingly little reaction. They remain firmly embedded in every specimen recovered, but the Roentgen ray shows a slight thinning of the bone about them. (7) The surface covers with connective tissue, a reversion of the cartilage from hyaline to fibrocartilage and then to connective tissue, which overlays connective tissue derived from the vascular spaces between the trabeculæ. (8) The response of the condyles to the presence of a rigid body projecting above the joint surface is to build up the condyle in its attempt to withdraw it, and prevent further injury to the opposing joint surface. This also takes place when the condyle is an autograft. (9) This growth is a true growth of bone, and the cartilage tends to retain its normal thickness. (10) The groove cut by a projecting nail or screw, in the opposing surface, covers over with hyaline cartilage, and the groove tends to fill up with bone as the projecting body is withdrawn by the growth of the condyle. (11) The line of fracture in the cartilage tends to cover over with cartilage, largely of the fibrocartilage type if it is narrow, with connective tissue if it is wide. (12) In autografts, empty drill holes fill with new bone, growing up from below, only to a very limited degree from the bone and cartilage in the graft; in living fragments, from the trabeculæ of the fragment, very little from the cartilage. The surface covers with the same kinds of connective tissue as do the nails and screws.

10. A Bacillus Isolated from Epileptics. — William Barclay Terhune makes this preliminary report. He states that feeling a deep interest in epilepsy, he undertook a study of individuals classified as epileptics in the East Louisiana Hospital for the Insane. It was decided that this investigation should be conducted from every possible angle; accordingly, case histories were reviewed, relatives questioned with a view if discovering the part played by heredity, personal injuries, illnesses, and psychic factors recorded. Accurate records were kept giving the number and description of the paroxysms in each patient, the nurses were interrogated regarding the habits and disposition of the epileptics in their care, and careful mental examinations were made. While he was in the midst of this work, Reed of Cincinnati published a paper definitely asserting that epilepsy was caused by a bacillus which might be isolated from the blood stream, which organism was found in large numbers in the colon of epileptics, and was demonstrable in the retroperitoneal glands. That epilepsy was of toxic origin was not a new idea, in consequence of the labors of Haig, Weber, Ferrani and many others. In view of the mass of statistical evidence pointing to the importance of the hereditary influences, and the traumatic factor, as well as the information gleaned from psychanalysis, he could not do otherwise than view with great skepticism the assertion that epilepsy was an infective process. Accordingly, the work embodied in this report was performed with the view of substantiating or disproving this assertion, and was begun with the preconceived idea that there was not any such organism as the *Bacillus epilepticus*. In summarizing he states that although he began this work profoundly biased in his opinion, as he believed that epilepsy was not bacterial in origin, he was forced to the conclusion that the bacillus which he had isolated, which was identical with the *Bacillus epilepticus* described by Reed, must be an etiological factor in epilepsy, in view of the following facts: A bacillus was isolated from 75 per cent. of the epileptics examined; it was present during and following a seizure but not during the intraconvulsive period, except in the case of one patient who was debilitated by ill health; it was not found in non-epileptics; it caused typical epileptoid convulsions in cats, during which death occurred, both when they were injected intravenously and when they were fed cultures of the organism; the organism might be recovered from the animal during the convulsion and after death.

11. Constipation and Intestinal Infection in Epileptics.—Charles A. L. Reed makes a reply to Caro and Thom and Wherry and Oliver, who have failed to find the *Bacillus epilepticus* in the blood of epileptics examined by them, and who therefore infer either that the organism does not exist, or if it does exist it is a contamination, or, in any event, it has nothing to do with "idiopathic" epilepsy. Reed states that the fact of the existence of the organism seems to be fairly well attested, since it has been isolated by a number of investigators in a large percentage of epileptics. The inference that the organism is a contamination is also unfortunate since it is scarcely likely that the different investigators should all have found the same contamination. The reason for the failure to induce convulsions in animals by Wherry and Oliver was due to the use of a subculture from a subculture which was probably not sufficiently potent to overcome the natural immunity of the animal. Reed also discusses the objections to his classifications of this organism. He presents the complete bacteriological records of his cases which Wherry and Oliver report from the standpoint of their individual observation, and in analyzing them finds that they show that positive findings were not made in every specimen taken. He finds several cases in which positive findings were not made until, in one instance, after the examination of the sixth specimen. The ratio of positive to negative findings is as 7 : 13. He cites one series of five and another of eight in which the first examinations proved negative. He says it will be seen from this that in the single examination of four cases and the three examinations of one case which Wherry and Oliver report it is not surprising that they obtained negative findings. Reference is also made to the work of Marie Bra, who in the early part of this century found an organism again and again in the blood of epileptics; other European investigators failed to find it, and disgusted with the treatment she received she forsook the scientific world and married.

1. A Series of Cases of Cerebral Embolism Consequent on the Reception of Gunshot Injury to the Carotid Arteries.—G. H. Makins bases this communication on the clinical history of 14 cases. He states that limited injuries are the most prolific source of origin of this class of cases. The presence of a definite perforating wound of the artery has been assumed from the existence of obvious signs, such as systolic arterial bruit, and arteriovenous murmur and purring thrill, the detection of a pulsating swelling in the course of

the vessel, or the occurrence of a secondary hemorrhage demanding surgical intervention. A non-penetrating injury has been assumed when none of the above signs could be detected, while diminution or abolition of the carotid or superficial temporal pulses has been regarded as evidence of obstruction or complete obliteration of the arterial lumen. Obliteration or considerable diminution of the distal pulse, although a corroborative factor, is by no means a necessary sign for the diagnosis of the formation of an arterial thrombus. The determination of the period which has elapsed between the reception of the injury and the onset of signs of cerebral lesions, while of prime importance, has proved of considerable difficulty. Reasoning from analogy, however, the rapidity with which a clot capable of causing cessation of hemorrhage from a ruptured artery in the limbs allows one to conclude with some confidence that a period of a few minutes would suffice. Hence very early development of symptoms need not be an occasion of surprise. In five of these 14 cases there were symptoms of damage to the cervical sympathetic nerve. Only one of these 14 patients died. Of the remainder, one was sent home practically recovered from an incomplete right brachial monoplegia and aphasia, while slight improvement had occurred in some of the others. The general impression, however, was not a favorable one. As to treatment, rest is the only resort; it might, however, be remarked as an important fact in support of the diagnosis (in favor of embolism as opposed to cerebral softening fqrom anemia) that in two cases in which subsequent complications necessitated ligature of the common carotid, neither patient suffered any increase in symptoms; in fact, one man's condition improved at once and the other made a steady improvement.

2. **Notes on the Agglutination Reactions with Oxford Standard Agglutinable Cultures.**—R. Donaldson and Barbara Clark present a study of the serum reactions of 275 patients, of whom 184 were soldiers. Of these latter 165 came from the Mediterranean, 18 from France, and one contracted paratyphoid in Reading. There were 91 civilians, of whom 53 were cases of typhoid or paratyphoid occurring during the Reading outbreak, while the remaining 38 were not suffering from the typhoid-paratyphoid group of diseases, but were used as controls. In their examinations they have used a slightly different technic from that used by Dreyer and have employed the Oxford standard agglutinable cultures throughout. These they have found thoroughly satisfactory. They believe their method the most accurate and the simplest of all agglutination methods where routine work is concerned. The great majority of their cases arrived with the diagnosis "enteric," whereas out of 115 cases only 13 per cent. at the outside could be claimed as true typhoid. The mortality among these typhoid cases was nil, and offers a marked contrast to the 15 per cent. mortality among 53 uninoculated civilians. Out of the 115 cases examined twice, 71.6 per cent. contained agglutinins for paratyphoid bacilli, and out of the whole number of military cases 60.3 per cent. agglutinated paratyphoid organisms. The impression that paratyphoid B infections are more common among these cases is probably more apparent than real, and is probably not to be explained merely by saying that one type of case was more common during certain months. The results obtained by the authors point to an explanation based on the time elapsing from the onset of the illness till the first agglutination. The nearer to the onset that the first agglutination is made the greater will be the number of positive A agglutinations. The further on one goes in convalescence before taking a reading the more likely is it that the less persistent A agglutinin will have disappeared, and consequently there will be a greater apparent percentage of B infections. These examinations did not furnish any clear evidence of coagglutination of A for B or vice versa, and there was no evidence of *B. typhosus* evoking coagglutinins for paratyphoid organisms in the lowest dilutions employed (1 in 27). Paratyphoid infections in persons inoculated against typhoid have acted as a stimulus to the agglutinin-forming mechanisms which had previously been called into being by a preventive T inoculation. The need should be emphasized for repeated agglutinations at intervals in the case, at least, of persons previously inoculated. It does not seem that any diagnostic inferrence can be drawn from a consideration of the titre in inoculated persons, where only one examination has been made. This study affords no evidence to support the view advanced by Tidy that marked pyrexia for some days is associated with diminution or disappearance of typhoid inoculation agglutinins. The civilian epidemic in Reading was not due to *B. typhosus* alone, but was complicated by a paratyphoid infection in a certain proportion of the cases. The source of infection was probably a military one. None of the 38 uninoculated controls showed any trace of agglutinins to typhoid, or paratyphoid A or B except four, and in one of these there was a history of contact.

4. **A New Remedy for Syphilis, Luargol or "102".**—N. S. Bonard writes of his experience with this preparation in Lock Hospital, where about 100 cases of syphilis at different stages were treated with luargol. All of these cases without exception have done well and the results are most satisfactory. The therapeutic effects have been more rapid than with salvarsan, neosolvarsan, galyl, novarsenobenzol, or neokharsivan. No serious complications or reactions have been observed. All symptoms of the disease have cleared up rapidly. The injections have been made with concentrated solutions of "102" by means of a 20 c.c. glass syringe. All out patients have been treated in the consulting room and have left immediately after. In the wards of the hospital the patients were not kept in bed after the injections. Frequent small doses have proved to be of greater benefit and to give better results than larger doses at longer intervals. The contraindications for luargol are the same as for other arsenical compounds. In acquired syphilis with primary, secondary, or tertiary symptoms without nervous complications, the following doses should be injected in a normal adult patient: 0.15, 0.20, 0.25, 0.30, 0.30, 0.30 gm., *i.e.* totally 1.50 gm. in six injections repeated every second, third, or fourth day. For a female patient in the same condition the following doses: 0.10, 0.15, 0.20, 0.25, 0.25, 0.25 gm., *i.e.* a total of 1.20 gm. A violent reaction may occur if the dose is too large, which is regarded as an anaphylactic crisis caused by the precipitate, which is the principal agent in the pathological manifestations. Sufficient alkalinization of the product will obviate the appearance of these nitroid crises.

5. **A Note on the Use of Perforated Celluloid in the Dressing of Certain Wounds.**—S. R. Douglas suggests for the alleviation of pain caused by the removal of dressings which have become adherent to the wound the employment of sheets of perforated celluloid. This material, which is rather too stiff to be conveniently applied to the irregular surface of the wound, was found to become perfectly safe and pliable, and at the same time somewhat elastic, after it has been soaked in a five per cent. carbolic solution for a few hours. The carbolic acid solution having been washed away with sterile salt solution, the softened celluloid can be applied to the wound surface and falls at once into all the

irregularities; any suitable dressing can be applied over it. On redressing the wound it is found: (1) That the celluloid lifts off the surface of the wound without causing any pain; (2) that all the discharges from the wound have passed through the perforations, leaving the surface of the wound quite clean; and (3) that the celluloid has regained its original stiffness, thus making an accurately fitting splint, which tends to keep the wounded tissue in a complete state of rest. After the celluloid has been taken off the wound it is cleansed in tepid water and again softened and sterilized by placing it in the 5 per cent. carbolic acid solution. Heavier sheets of celluloid treated in this way have been found to make excellent splints.

5. Septic Endocarditis; Intravenous Injection of Eusol; Recovery. J. Allman Powell.

1. Note on Weil's Disease (Spirochætosis Icterohæmorrhagica) as it Has Occurred in the Army in Flanders.—Adrian Stokes and John A. Ryle state that about 15 cases of Weil's disease have come under their observation and they have been able to confirm the findings of the discoverers of the cause of this disease. In two cases they have succeeded in infecting animals, and these have shown the characteristic pathological changes. In each instance the guinea pig was found to have the spirochætes in large numbers in the liver and blood. Two of four experiments done on the sixth day of illness were positive; no positive results were obtained after the sixth day. The infected guinea pigs became ill on the fifth day after injection, in one case, and on the seventh day in the other. The lungs of these animals presented the small hemorrhagic spots, like the wings of a mottled butterfly, which is one of the most important changes in the diagnosis of the disease. The authors think that, while the experimental facts which they present are meagre, they are sufficient to show that the cause of epidemic jaundice in Flanders is identical with that found in Japan, and to emphasize that it is important that the infective possibilities of Weil's disease be recognized. The clinical histories of individual cases are given, from which it appears that there are both mild and very severe types of the disease. The jaundice, weakness, and pain in some cases have been slight and of not long duration. On the other hand, there were three deaths in this series and two other patients were very ill.

2. Heart Affections in Soldiers, with Special Reference to Prognosis of "Irritable Heart."—J. C. Meakins, J. Parkinson, E. B. Gunson, T. F. Cotton, J. G. Slade, A. N. Drury, and Thomas Lewis present this memorandum based on observations made at the Military Hospital, Hempstead, where 200 beds have been set aside for soldiers suffering from heart affections. Of 251 patients, 113 were discharged from the army within a few weeks of admission. This group contained 31 cases of mitral stenosis, 7 of mitral stenosis and aortic disease, 22 of aortic disease, and 53 of myocardial disease with or without enlargement and with or without mitral incompetence. The graduated exercises and marches by which some of the patients are returned to duty or fitted for civil life are described. With reference to the prognosis, they state that the proportion of favorable results is highest among men who have broken down in health on active service. Men who develop their symptoms while training at home are distinctly unfavorable subjects. The prevalence of rheumatic or choreic history amongst cases of irritable heart is too high to be a matter of coincidence (19 per cent.); it suggests the presence of early rheumatic heart lesions in many of these soldiers. Patients in whom there is such a history rarely reach the higher grade exercises, though their physical signs do not differ from the remainder. The majority have to be discharged as permanently unfit. Of the irritable heart cases, 46 per cent. gave a history of symptoms dating back prior to enlistment. The longer the history the worse the prognosis; patients in whom the history is of years standing make little progress; those soldiers are most likely to return to duty in whom the history is of a few months' duration.

4. Some Principles of Investigation in Blood-Pressure Problems in Health and Disease.—James M. McQueen deplores the lack of method shown by some clinicians in the choice and arrangements of their observations on blood pressure. He points out that the feature to be studied in the circulation in health and disease is the power of the heart in conjunction with changes in the peripheral blood field to adapt itself quickly and efficiently to extra strain. If a satisfactory knowledge of the heart and peripheral circulatory system in the human subject in health and disease is to be gained it is necessary to examine and record the changes in the systolic, in diastolic, in pulse pressure range, rate of heart beat, and rate of respiratory rhythm during the strain thrown on the heart by exercise, not after it is over. The systolic pressure can be estimated during exercise either by the auditory or the tactile index, but the diastolic index is estimated by the auditory index alone. Consequently it is best to adhere to the auditory index for both measurements. In making the examinations the subject is placed on his back on a polished table and the exercise consists in rhythmically drawing up his feet and legs as in swimming on the back. The mildness of this exercise depends upon the length of time it is kept up. It is also possible to examine the circulatory phenomena during exercise in the erect posture by the auditory method, the exercise employed being that of working a silent lathe with one foot. By these methods it is found that the ranges of blood pressure, both systolic and diastolic, in both healthy and unhealthy subjects vary greatly. It is obvious that the response to a given amount of work of normal adults with a blood pressure, say of 130 systolic and 75 diastolic, and a rate of heart beat, say 78, should be investigated. The author believes that in cases with departures from the normal by testing them against the performance of a given amount of work we may be able to solve some of the problems as to how nature adapts both the heart and the peripheral circulation so as to overcome initial defects. Until we know the significance of various levels of pressure, systolic and diastolic, with various rates of heart beat, and respiratory rhythm, a mere chronicling of measurements in countless clinical lectures is without significance.

5. Septic Endocarditis: Intravenous Injection of Eusol; Recovery.—J. Allman Powell reports the case of a girl, 13 years of age, in whom an erysipelas of the right foot and leg was complicated by septic endocarditis. Two injections of antistreptococcal serum were administered. The first seemed to be followed by some improvement; after the second the patient became rapidly worse. As a last resort it was decided to give her eusol [a solution of 12.5 grams each of calcium chloride

and boric acid in 1 liter of water] intravenously. Forty c.c. of eusol was administered, preceded by 300 c.c. normal saline. At the time of the injection the patient was apparently dying. After the injection she perspired freely and an hour later had another rigor. From this time she gradually improved, and several months after was apparently well except for some rapidity of the pulse and anemia. No blood culture was made so the diagnosis was not proved, but clinically the case was typical of acute sepsis of the blood stream.

Journal de Médecine de Paris.

September, 1916.

Treatment of the Carriers of Diphtheritic Bacilli.—Labbe and Canat cite abundant evidence of the tenacity of this bacillus to remain in the throat, especially after proliferation. After an attack of diphtheria, 50 per cent. of victims are carriers for one month, 40 per cent. from one to two months, and 10 per cent. from two to three months. Carriers have remained carriers for 458 days, 669 days, etc. In war times it is a great burden to keep carriers of any disease isolated for weeks. The most vigorous and protracted sterilization may not dislodge all of the bacilli until perhaps three months have expired. Antisera used in solution or insufflation perhaps represent an advance, but are still on trial. The authors make use of the following system: During the first postdiphtheritic three-month period, when bacilli of all lengths may be present, the throat is irrigated abundantly with Labarraque's solution 30 per cent. in water, while a 10 per cent. resorcin ointment is introduced into the nostrils. Both remedies are exhibited twice daily. The throat is also swabbed with iodized glycerin 1 per cent. Of twenty-nine patients thus treated, twenty-four were freed from bacilli in an average of thirty-one days. The extremes were fifteen and forty-eight days. In the other five the average persistence was over forty days. (As a matter of fact, one was discharged still a carrier on the seventy-fifth day and the other four under the same conditions on the ninetieth day.) In a second period the antimicrobic serum was used on all carriers, thirty-five in number, the powder being insufflated into the nose and throat. The bacilli disappeared in from nine to sixty days, save for one case in which they persisted for ninety-five days. The average was twenty-four days. Naturally the two methods could not be applied jointly. We see here a slight advantage of the serum over the antiseptic treatment.

Specific Treatment of Scarlatina with Sodium Salicylate.—Ramond and Schultz refer to the disease as it occurs among the troops. Originally the treatment was purely symptomatic, and consisted partly of red light. It seemed impossible to jugulate a violent attack, and the authors sought a remedy which would exert a quasi-specific action directly upon the disease. On account of some similarity between this disease and acute articular rheumatism, the salicylate of sodium was the first to suggest itself. The so-called rheumatic manifestations of scarlatina respond readily to this drug, and this rheumatism is clearly the disease itself and not a complication. The drug is indicated in all types of the disease, and should be given always in apyretic cases in which dangerous complications may develop. It should be given from the start to the finish of the fever and general reaction. Allowing three days for this, it should be given for two days more. After the fifth day it should be discontinued, and resumed from the fifteenth to the twentieth day, when late complications are due. These arise in part from a reanimation of the scarlatinal virus, which is at once controlled by the salicylate. If these complications were really due to the streptococcus the salt would exert no power over them; however, a simple infection may readily be grafted upon the primary disease if the remedy be not promptly given. The dose is about 6 grams per day, increased to 8 grams or more if required. Scarlatina, like acute rheumatism, is characterized by nocturnal exacerbations; hence the drug should be followed up during evening and night. When the treatment is resumed at the fifteenth day the dosage need not be as large. As already stated, the fever, under the action of the drug, subsides by the third day. If defervescence does not occur we may accuse some secondary infection or a complication like bronchopneumonia. The throat lesions rapidly undergo involution, but, with the recrudescence of the disease, may reappear in an aggravated form. It is purely a scarlatinous symptom, and is rapidly controlled by the salicylate. The early nephritis of scarlatina is not a serious manifestation, but the later form is always uncertain. The salicylate may abort it if given in time, but if it have several days' headway the drug should be given cautiously, in relatively small doses, lest the kidneys be unable to excrete it. If it can pass the kidneys the dose may be increased. But the drug evidently has no salutary effect on the organ, and is given for the sake of the disease as a whole. On all other manifestations of the disease the drug behaves more or less as a specific.

Treatment of Pertussis.—Satre discusses the subject with candor. He gets a certain amount of relief from bromoform, which diminishes the intensity of the cough and vomiting. Relief must not be looked for until two, three, or four days after the treatment has begun. For children under 2 years of age he prefers terpene. A third trustworthy medicament is quinine, pushed in broken doses. A child of five receives 1 gram in twenty-four hours. The drug is given persistently for several days only. If benefit has been obtained he stops its use or continues it in much smaller doses. If the results of the sulphate are negative, he then gives the chlorhydrate, bromhydrate or carbonate. His reliance upon it is such that in case of intolerance by the mouth he injects hypodermically the bichlorhydrate. In several days the course and severity of the disease should be favorably influenced.

Clinical Notes on 289 Cases of Icterus Observed in an Ambulance Service.—Gimbert, at the Medicochirurgical Reunion of the V Army, stated among the troops all ages suffered and cases occurred almost equally in all seasons. Among predisposing causes are previous sojourn in the colonies, abuse of meat diet, vaccinations performed at too frequent intervals. Myalgias and arthralgias are often seen at the onset of jaundice, and transitory albuminuria is often present. When enlargement of the liver exceeds 15 or 16 cm., one may think of destruction of the hepatic cells or intrahepatic disorders of circulation. Bradycardia and low-tension pulse are often present and dilatation of the heart may be very frequent. Intense anemia may follow the jaundice, accompanied by slight enlargement of the spleen, suggesting the possibility of a critical hemolysis. The temperature, elevated at first, becomes in turn a permanent hypothermia. All the clinical types have been observed, from simple congestion of the liver to fatal icterus gravis (two cases). Prolonged icterus and relapsing icterus were also seen. The prognosis may be grave, and advanced age and intemperance are largely

responsible; these factors always aggravate the disease. From the therapeutic viewpoint sodium salicylate is the best cholagogue, while urotropin and calomel are the best antiseptics. Adrenalized serum has rendered excellent service. The best regimen has appeared to be legume broth and low-protein diet. A milk diet was inferior to the preceding.

Utilization of the Cochleo-Orbicular Reflex in Deafness.—Gault's material consisted of soldiers who were completely deaf, partially deaf, suspected of deafness. These have all been tested in the usual manner, including search for the nystagmus reflex by excitation of the labyrinth (vestibular). Can excitation of the cochlea also produce this reflex? A cochlea-orbicular reflex has been known for many years. It may be produced by certain brusque procedures, such as firing a pistol close to the ear. The sound is transmitted to the organ of Corti, reaches the cochlear nucleus in the bulb, is irradiated by the facial nerve, and causes a contraction of the superficial facial muscles, and especially of the orbicularis palpebrarum. This contraction varies much in degree, but if it is present at all it guarantees that the organ of Corti and acoustic nerve are intact, so far as gross lesions are concerned. If, on the contrary, the reflex is suppressed, the vestibule is destroyed. Marked reduction in degree of the reflex suggests a minimal lesion in the vestibule. To practise the test the author uses the horn of a bicycle, which is not burdensome to the patient yet well suited to excite the organ of Corti. The eyelids are watched with a strong lens to discover the slightest flicker. The horn is blown about 2 meters from the ear, and must be on a prolongation of the biauricular line. The meatus must be plugged with cotton soaked in vaseline, and cardboard or some similar substance placed in front of the ear. The eye observer gives a signal to the horn blower. At the very first sound the former notes through his lens perhaps a minimal contraction of the orbicularis. The subject is unable to resist this action of the muscle. If total deafness from organic disease is present, the reflex is entirely absent. However, in a heredosyphilitic patient with apparent total deafness, the horn when blown at the distance of 1 meter elicited a feeble response. In traumatic total or subtotal deafness listed as due to shell shock the reflex is not entirely extinguished, and unconscious simulation is often revealed by the test. Many of these patients will promptly recover, but it is best to "let them down easily" and treat them as if they were actually deaf, promising good results from certain remedies, which duly appear, to the wonder of the patient. In some of these subjects with marked psychic trauma both the cochlear and vestibular reflexes are normal, but there is a fixed idea of deafness. These men must not be mistaken for malingerers. A so-called deafness by inhibition of cortical origin is often seen and is curable by therapeutic suggestion. Of 500 to 600 cases of "traumatic" deafness of mostly early appearance, but a single case of total permanent deafness was noted despite the frequent diagnosis of labyrinthitis. In malingerers of total deafness, who are more rare than is generally believed, the cochleopalpebral reflex exposes the deception.

Gazette Hebdomadaire des Sciences Médicales de Bordeaux.

September 24, 1916.

Treatment of Post Chloroformic Vomiting.—Jeaneney states that there are two forms of this accident. One is of psychic origin and is of a benign type—only mucus or bile being evacuated. The patients may be obsessed with the idea that they must vomit, or may simply be influenced by some association of ideas or even be nauseated by the smell of chloroform. The other type of vomiting is known as the toxic, and produced by the action of some poison on the vomiting center, usually chloroform itself. The patient may be hypersensitive to such toxic influences. Ranking with this type as a serious form of vomiting is that produced by acute postoperative dilatation of the stomach. The toxic cases may be conservative for when vomiting is checked by treatment the patient still feels malaise and sense of weight in the epigastrium relieved only by vomiting which may supervene about the third day, often when a purgative is given. In toxic vomiting we see violent accesses occurring without apparent cause, rebellious, frequent, with a peculiar odor of the breath. Slight icterus now appears, with delirium and convulsions and eventually bradycardia. The syndrome is due to the great fragility of the hepatic tissues after chloroform. The prophylaxis of chloroform vomiting consists in the milk regimen and the use of a purgative. The stomach must remain empty for some eight hours. This precaution works wonders. In veterinary practice apomorphine is given. The purest and best chloroform must be used. It must have been recently distilled. Much must depend on the anesthetist as some of them hardly ever see vomiting. After the operation nothing is taken into the stomach for ten hours when a spoonful of water is first given, then liquid diet, semiliquid diet, lactovegetarian diet up to full regimen. When psychic vomiting appears, a combination of eucalyptol and menthol is given by the mouth, while oxygen is inhaled. Any powerful essence or aromatic substance may be smelled. Spirits of cologne inhaled from a mask is a favorite remedy in England. If these measures fail the ordinary substances given to check vomiting may be tested in succession, as ice, charged water, etc., etc. The author is not enthusiastic over this class of remedies, considering the psychogenic nature of the vomiting. In toxic vomiting the first indication is gastric lavage. After a due interval hot drinks are given, sweetened or alkalinized, and later milk. Next day a sodium sulphate purge is given. If the case is desperate blood transfusion is practised. It must not be forgotten that we do not wish to suppress the vomiting entirely, but to reduce its degree notably.

Reflex Disturbances and Cerebral Insufficiency.—Mézie like others has noted reflex disorders in a great variety of wounded soldiers, comprising contractures, pareses, paralyses, hypotonias. They are accompanied by troubles of sensibility, trophic disturbances, vasomotor and thermic disorders, and alterations in the blood pressure, as determined by Pachon's oscillometer. In addition, such conditions as edema, refrigeration, cyanosis, profuse sweats cause suspicion of reflex disorders. According to Babinski and Froment the wound of the extremity produces these reflex disturbances chiefly on the corresponding side through the intermediary of the cells of the cord, some of which are activated and others muffled. Cerebral fatigue acts as a contributory cause. The author would make cerebral insufficiency a most important factor. In these patients there are numerous evidences of this insufficiency both physical and mental. The condition may be due to mental over-activity and fatigue or to commotion. Persistent insomnia and repeated emotions play their part as does an innate cerebral inferiority. The various forms of physical therapy give the best results in treatment.

Casualties Among the Canadian Troops.—The total number of casualties among the members of the Canadian forces up to the middle of October are reported as 52,025, divided as follows: Wounded, 37,939; killed in action, 8,133; died of wounds, 3,120; died of sickness, 452; missing, 2,381.

Book Reviews.

THE ART OF ANÆSTHESIA. By PALUEL J. FLAGG, M.D. Lecturer in Anæsthesia, Fordham University Medical School; Anæsthetist to Roosevelt Hospital; Instructor in Anæsthesia to Bellevue and Allied Hospitals, Fordham Division; Consulting Anæsthetist to St. Joseph's Hospital, Yonkers, N. Y.; Formerly Anæsthetist to the Woman's Hospital, New York City. Pp. 341 with 1136 illustrates. Price, $3.50. Philadelphia and London: J. B. Lippincott Company, 1916.

ALMOST anyone can hold a cone and pour ether on at the word of command of the operator but, as Flagg says, the proper administration of an anesthetic is more than a mere mechanical performance and the art of anesthesia is acquired by becoming familiar with the laws which govern its administration and by developing the ability to properly correlate and apply these laws. With these facts in mind the author has discussed the subject most intelligently and has elaborately presented the fundamentals of correctly administering anesthetics of various kinds and in various sequences.

After an introductory historical sketch the author proceeds to the classification of anesthesia, its characteristic signs and its administration by the various methods and agents ordinarily employed. Each of the three types of anesthesia—general, local, mixed—is discussed in detail, often in most exhaustive fashion; and this applies particularly to the 200 odd pages devoted to general anesthesia. This is considered from every angle. The stages of anesthesia—induction, maintenance, and recovery; the signs of anesthesia as shown by changes in respiration, color, muscle symptoms, the behavior of the eye reflexes, and the pulse; the methods of administering ether—oral insufflation, intrapharyngeal, intratracheal, oil-ether rectal, intravenous; general considerations and the technique of administering ethyl chloride, chloroform, nitrous oxide, and the various sequences—all these subjects are treated with much detail. Methods of local and mixed anesthesia are then briefly outlined, this closing Part I of the book. Part II, "Bearing upon factors incidental to the actual administration of the anesthetic," discusses preliminary medication, post-operative treatment, emergency anesthesia, etc.

The book's greatest fault lies in its prolixity and we should say that the text could be condensed at least one-third without leaving out anything of vital importance. Circumlocution and redundant words and phrases abound. Hence, while the embryo anesthetist cannot fail to profit greatly by reading the book as it stands, it would be much more valuable as a teaching instrument after proper condensation and a little friendly editing; for the English construction is not always what it should be.

ASEPTIC SURGICAL TECHNIQUE with Especial Reference to Gynecological Operations, Together with Notes on the Technique Employed in Certain Supplementary Procedures. By HUNTER ROBB, M.D., formerly Professor of Gynecology, Western Reserve University and Gynecologist-in-chief to the Lakeside Hospital, Cleveland, Ohio; Fellow of the American Gynecological Society and of the American College of Surgeons, etc. Fifth edition, revised. Octavo of 292 pages, with 44 text figures and 24 plates. Price, $2.00 net. Philadelphia and London: J. B. Lippincott Company. 1916.

IN the preface to the first edition, which appeared twenty-two years ago, it is stated that the technique recommended is in the main that practised in the gynecological and surgical departments of the Johns Hopkins Hospital. Certainly many radical changes in technique have been made at the Johns Hopkins Hospital as well as everywhere else in the past twenty years; but starting with that excellent model, occasional revisions have made it possible for the author to follow the same general scheme and still incorporate new material and alter the old in accordance with the best teachings of the day.

The author first discourses upon the importance of a bacteriological training to the surgeon; and makes the point that the trained bacteriologist will have exalted ideas of surgical cleanliness, and cannot fail to see the many inconsistencies that occur during the majority of operations. Sepsis and wound infection, the microorganisms generally concerned, asepsis, antisepsis, the principles of sterilization, dry and moist heat, fractional sterilization and chemical disinfection are taken up in order. This is preparatory to the actual business of the book—instruction in the practical application of the principles of sterilization as concerns gowns, dressings, instruments, sutures, etc.; the care of instruments, rubber gloves, drainage and other materials; the preparation of the operative field; the preparation that must be made for operations in private houses; the preparation of the patient for major and minor operations; postoperative care; and numerous other matters that must be understood by the nurse, operator, and assistants in order that operations may be conducted with that aseptic technique which is the desired goal of most competent operators to-day and the despair of many. In the latter part of the book are found a number of chapters on examinations of various kinds. Some of these would be improved by further revision; and this applies especially to that on the examination of the bladder and ureteral catheterization, for this chapter is in many respects far out of date. The final chapter, on endometritis, has been added in this edition. Why the author has added twenty-seven pages on this subject is beyond our comprehension. It seems to us entirely out of place in a work of this sort, especially as it is the sole representative of the discussion of disease affecting a particular organ.

For the nurse, for the interne, and, above all, for the man who is occasionally called upon to operate and who has not had the advantage of rigid hospital training, this book should be of great value.

THE CLINICS OF JOHN B. MURPHY AT MERCY HOSPITAL, CHICAGO. Volume V, Number 3, June, 1916. Octavo of 178 pages, with 44 illustrations. Price per year, paper, $8.00; cloth, $12.00. Philadelphia and London: W. B. Saunders Company, 1916.

THIS is a better issue of the Clinics than has appeared in many months. With the exception of one case of infective costal perichondritis, bone and joint cases are conspicuous by their absence. This is, in itself, cause for rejoicing; for our appetite for clinical lectures on bone and joint diagnosis and operative technique was long ago satiated. In this volume about thirty-five clinical cases are discussed and every one should be of interest to the general practitioner, for most of the cases are such as he is apt to meet any day in his practice. There are also a number of valuable tables, diagnostic and otherwise, in connection with certain of the subjects.

MODERN MEDICINE AND SOME MODERN REMEDIES. Practical Notes for the General Practitioner. By THOMAS BODLEY SCOTT, Author of the Road to a Healthy Old Age. With a preface by Sir LAUDER BRUNTON, Bart., F.R.S. Price, $1.50. New York: Paul B. Hoeber, 1916.

THIS little work consists of four essays, devoted respectively to disorders of the heart, arteriosclerosis, endocrinology and chronic bronchitis. The first thing to attract the reviewer's attention is the fact that the essays are not reprints of journal articles, but have been independently composed. The author, a clinician of wide experience, has endeavored to popularize among the ranks of the busy practitioner, some of the latest developments of internal medicine, all of which have reference directly or indirectly to those disorders of the circulatory system which continue to be the great menace to those past middle age. Therefore it is hardly necessary to dwell on the timeliness of the book. Sir Lauder Brunton's service as sponsor to the book is unnecessary, but welcome. In his preface he bitterly assails the Germans for robbing mankind of the treasures of the University of Louvain.

ULTRA-VIOLET LIGHT BY MEANS OF THE ALPINE SUN LAMP. Treatment and Indications. By HUGO BACH, M.D., Bad Elster, Saxony, Germany. Authorized Translation from the German. Price, $1.00. New York: Paul B. Hoeber, 1916. pp. 114.

THIS little work is properly devoted to the indications for the use of ultra-violet light lamps and the technique for carrying out the same. Not much space is devoted to the principles and construction of the apparatus, with which the physician is presumably sufficiently familiar. The raison d'être for the book appears to be associated with the use of the lamp for general disorders, as distinguished from local, superficial ailments. Here belong tuberculosis, chlorosis and anemia, leukeuria, arteriosclerosis, cardiac and renal disease, obesity, diabetes, furunculosis, gout, chronic rheumatism, neurasthenia, etc., etc. In this class of cases the lamp is regarded as an understudy of direct solar light whenever the latter is not fully available.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Twenty-Ninth Annual Meeting Held at Indianapolis September 25, 26, and 27, 1916.

THE PRESIDENT, DR. HUGO O. PANTZER, INDIANAPOLIS, IN THE CHAIR.

Appendicular Abscess Complicated by Hemorrhage and Death.—Dr. MAGNUS A. TATE of Cincinnati spoke of this condition as rare. The patient was a young woman who had her first attack. Her abdomen was opened through the right rectus, and drainage was profuse for six days. At the end of the tenth and eleventh days her condition was good. On the twelfth day she complained of pain and nausea. On the morning of the thirteenth day there was hemorrhage from the wound, and on the fourteenth day her condition was alarming, death occurring the same evening. Autopsy revealed a gangrenous sac, the size of a dollar, which was found in the mesentery, probably the site of hemorrhage.

Dr. ALBERT GOLDSPOHN of Chicago said that this case reminded him of an experience he had after a vaginal hysterectomy in a septic case a number of years ago where, after a normal course following operation, the patient began to bleed about two weeks after the wound had nearly closed. After futile attempts to stop the hemorrhage by local tamponning and the use of clamps, he saved the patient's life by doing an abdominal section and ligating the internal iliac arteries.

Drainage for Pus Conditions in the Pelvis During Pregnancy.—Dr. FRANCIS REDER of St. Louis stated that the most frequent cause of a pus accumulation in the pelvis during pregnancy must be attributed to a diseased appendix. A pelvic abscess was very insidious, with the exception, perhaps, of a subphrenic abscess. The reason for this was that the diagnosis of appendicitis was often obscured by pregnancy. If the pains and frequent indispositions, which usually accompanied the pregnant state, were not closely scrutinized and correctly and promptly interpreted by the physician, the primary clinical picture of an attack of appendicitis might be readily overlooked, and only recognized when the more serious phases of the disease had manifested themselves. Pregnancy did not in any way predispose to appendicitis, but on account of the anatomical changes which took place in the pelvis during pregnancy, appendicitis might terminate in a pus formation more rapidly than in the nonpregnant state. A close study of the symptoms of an appendix lesion during pregnancy might bring out some clinical points which differed from the usual clinical picture as it was found in women who were not pregnant. For instane, before any pus formation had taken place, the pulse and temperature might show little or no change. The pain was usually located in the epigastric region and remained there until the disease had reached the stage when all pain ceased. The triad of Dieulafoy was often so obscured by other conditions that it was usually blurred, and its presence therefore overlooked. Even in an advanced pregnancy a readily recognizable rigidity of the right rectus was seldom encountered, and only exceptionally did palpation reveal a tender spot over McBurney's point. Nausea and vomiting, two alarming symptoms in an attack of appendicitis, counted for naught during pregnancy because they were frequently associated with the toxemia of the latter condition. The most satisfactory and convincing evidence as to the presence of pus in the pouch of Douglas could be obtained by a rectal examination. If the accumulation was considerable, no difficulty should be experienced in promptly detecting a fluctuating mass, even if the examining finger was inexperienced. Surgery during the pregnant state must have its limitations and they must be more respected in the latter stage of gestation. An abdominal operation, for example, could be done with less risk of interrupting pregnancy before the fourth month than after. Furthermore, the thoroughness with which an operative measure during early pregnancy could be carried out was fraught with less danger than in the later stages. Great antipathy still existed as to attacking a pelvic abscess through the rectum, largely because of the likelihood of infecting the abscess cavity. This was doubtful, inasmuch as it was one of nature's ways in relieving the organism of a pus accumulation in the pelvis. Patients relieved in this manner had usually suffered no untoward results and their recoveries had been satisfactory.

Dr. HERMAN E. HAYD of Buffalo, N. Y., said that in cases of appendicitis complicated with pregnancy miscarriage was apt to take place. Miscarriage was liable to occur in typhoid fever complicating pregnancy. Undoubtedly a bacteriemia was established, and the fetus was made ill by reason of the infected blood, and as a result the woman had a miscarriage. The point the essayist brought out of opening the abscess through the rectum was a good one.

Dr. W. A. B. SELLMAN of Baltimore stated that he had had experience with two cases of appendical abscess complicating pregnancy. One woman was pregnant four months, and the other six months. One method of dealing with these abscesses was that suggested by the essayist of opening through the vagina posteriorly into the cul-de-sac and by that means reaching the abscess. The second method was opening the abscess through the rectum. He selected the abdominal route, made an incision, drained the cavity, leaving the drainage tubes in. His experience was that in appendical abscesses it was necessary to drain the cavity for a longer period than that suggested by Dr. Reder.

Dr. ROLAND E. SKEEL of Cleveland said that as regards making a puncture through the rectum in these abscesses he had used that procedure for ten years, but he would emphasize the fact that there must be an abscess cavity. If there was no abscess cavity with a thin wall, it would be dangerous on account of peritonitis or rectal infection. He could recall cases of appendicular abscess which opened and drained through the rectum spontaneously.

Dr. REDER, in closing, said that in these cases he contented himself with draining and did not care to use a split tube for fear some irritation by pressure might excite infection.

Rupture of the Uterus; Sepsis; Operation; Recovery.—Dr. RUFUS B. HALL of Cincinnati reported a case of rupture of the uterus, followed by sepsis, with a walled off abscess, which was operated upon thirty-seven days after delivery. The patient made a slow but satisfactory convalescence and was now perfectly well. Rupture of the uterus during labor was a rare and dangerous accident. It was so fatal that it was our duty to report every case in detail, whether the patient recovered or not, that the profession might profit by the facts revealed in each individual case. He asked if it was possible that an unrecognized small rupture, causing leakage into the abdomen, might not be more frequent than was generally believed. The case reported would suggest that as a possibility, because there were no symptoms connected with the case that would suggest rupture of the uterus, and it was not suspected until revealed at the time of the operation.

Rupture of the Uterus in Cesareanized Women.—Dr. JOHN NORVAL BELL of Detroit drew the following conclusions: (1) A cesareanized woman was always in danger of uterine rupture in subsequent pregnancies and should be under careful observation for the last half of her gestation. (2) In case her puerperium following the first section was afebrile she might be allowed to go to term if she could be in the hospital for the last month of gestation; otherwise the labor should be anticipated and operation done at least two weeks prior to term. (3) Implantation of the placenta over the scar area undoubtedly increased the danger of rupture, as did also an afebrile puerperium following operation.

Rupture of the Cesarean Scar.—Dr. ABRAHAM J. RONGY of New York City drew the following conclusions: (1) Spontaneous rupture of the cesarean scar occurred in about three per cent. of cases. In most instances rupture took place during labor. Not frequently it took place during the latter half of pregnancy, especially in the last six weeks. (2) We had no means by which we could judge the strength of the scar. Rupture would occure in cases which ran an afebrile course and in which union of the wound was apparently by first intention. (3) One-third of all cases that were operated for reoperated section showed evidence of inflammatory reaction in and about the uterine wound. The result in such cases was a weakened scar. (4) Proper suturing of the uterine wound and exact approximation of the edges would not always prevent subsequent rupture of the scar. (5) The mortality rate of repeated section was smaller than that of primary cesarean section, because these patents were more carefully watched by competent men. (6)

A patient who had had a cesarean section should not be allowed to go through a tedious or severe labor. If labor did not progress rapidly, repeated section should be performed. (7) When advising a patient to have a cesarean section the management of subsequent pregnancies should be taken into consideration and discussed with one of the members of the family. (8) As a general rule, it might be stated that fully seventy-five per cent. of women who had had a cesarean section were delivered by repeated section during their subsequent labors. (9) The obstetrician should always bear in mind that cesarean section created a new problem for the woman, and therefore he must carefully weigh the indications before he decided upon the abdominal route. He must remember that the dictum, once a cesarean section always a cesarean section, held true in fully seventy-five per cent. of cases.

Dr. PALMER FINDLEY of Omaha said that if ninety-seven women out of a hundred went through labor with a cesarean scar successfully without intervention, the thing to do was to put the woman in a hospital, if possible, and be ready to interfere, but we should not adopt the method of performing a cesarean operation on every woman who had had a previous cesarean scar in the uterus. He did not think we should be guided by any three per cent. of chances except this: we should take every precaution to safeguard the woman in the event of imminent rupture of the scar.

Dr. J. HENRY CARSTENS of Detroit said he had had about fifteen patients upon whom he had performed cesarean section a second time. In all of the cases there was pelvic deformity. There was not one of them in whom the operation was performed for placenta previa or eclampsia. He made it a point to have these patients go to the hospital early, if possible, and operated on them two weeks before the expected time of labor. He hesitated twice before he would sterilize a woman who had had no children.

Dr. HENRY SCHWARZ of St. Louis said that he endorsed every word Dr. Findley had said. Within the last year he had delivered two women through the natural passages. One was a woman on whom Dr. Webster of Chicago had performed a cesarean section on account of obstruction to delivery by an ovarian tumor. He did a cesarean section on the other patient years ago. The woman was brought to the hospital with a temperature of 104°; she was intensely sapremic, there was an offensive discharge, with a dead macerated fetus in the uterus. He removed the fetus. The patient was a young woman, and this was her first pregnancy. After emptying the uterus and removing a subserous fibroid which was situated on the left side of the uterus, close to the external os and blocking the pelvis, and after removing a smaller fibroid near the fundus, he closed the uterus, because the woman was young and had had no children. He delivered this woman about seven months ago through natural passages.

Dr. JAMES E. DAVIS of Detroit said that the problem from a pathological standpoint was this: First, we had a reduction of muscle tissue, a degradation of a normal tissue, then we had a degradation of the connective tissue by the interposition within the connective tissue cells of syncytial cells. The connective tissue, while it might be in certain instances as strong as the muscle tissue, yet was not as resistant to the syncytiolysins which were formed from the syncytial cells, and wherever we had syncytial cells we had a tissue of very low resistance so far as its ability to withstand pressure was concerned.

Dr. MAURICE I. ROSENTHAL of Fort Wayne said that the important thing was infection, and that infection was predisposed to by intrauterine pressure. If the lochia was kept free from the internal surface, the entire suture line closed owing to the absence of the intrauterine pressure, and that was a point in safeguarding against the infection of the wound and in securing perfect wound healing.

Dr. IRVING W. POTTER of Buffalo said that he had done cesarean section on a number of patients a second time without any trouble. One could not see the scar in the majority of cases from the outside, but if one felt from below up one would find a thinning in many of the cases, although it was not enough to make any special difference.

Dr. HERMAN E. HAYD of Buffalo said he would like to ask Dr. Bell why he removed the uterus in this case? Why did he not sew it together instead of removing it?

Dr. BELL, in closing, said he must confess he was afraid the woman might have died. In order to sew the uterus he would have been obliged to freshen both edges entirely, because there was a scar, and except for the fibromuscular bands across, he would have been obliged to remove the surface of the normal part. He thought he could do the other operation better.

Dr. RONGY, in closing, said that he never sterilized a woman unless she had had two children. He did not do hysterectomy in these cases, but resected the tubes on either side and then embedded the cut ends of the tubes in the wall of the uterus. That was a safe procedure.

Gunshot Wounds of the Abdomen in Pregnant Women.—Dr. LEWIS F. SMEAD of Toledo, Ohio, reported the case of a woman shot through the abdomen with the recovery of both mother and child. The bullet perforated the colon and the uterus of the mother, the placenta, and the hand of the child. Gunshot wounds of the abdomen were more dangerous during pregnancy than at other times. The abdomen should be opened in all cases, if possible. The uterus at full term should be emptied by cesarean section and at earlier periods if the organ was badly injured. A uterus during labor was likely to spread any infection which was free in the abdomen and a pregnant uterus was therefore a menace to the patient if peritonitis developed. The uterus would usually be emptied by cesarean section or hysterotomy because the abdomen was open. Hysterectomy was usually not indicated in gunshot wounds of the abdomen unless the uterus was badly lacerated. Drainage should always be used in these cases and irrigation very rarely. He gave an abstract of about thirty cases of gunshot wounds of the abdomen in pregnant women.

Dr. JOHN D. S. DAVIS of Birmingham, Ala., said that he rose to report a case of gunshot injury in a woman pregnant three and a half months. She was handling a small rifle when it went off and shot her through the abdomen, producing twenty-five perforations, six through the transverse colon and nineteen through the small intestine. She was brought a distance of eighty-five miles. He saw her twelve hours after the reception of the injury. There were five perforations on the mesenteric border of the small intestine, and two perforations on the mesenteric border of the transverse colon. He closed back the serosa and turned in the musculature and put the serosa over that. Instead of doing two resections of the gut, he took out five feet of the intestine between the nineteen perforations. She recovered and gave birth to a living child at the ninth month.

Version with Report of Five Hundred Cases.—Dr. IRVING W. POTTER of Buffalo, N. Y., stated that in the advocacy of all procedures we should have a clear idea of the results. In these 500 cases there was not a maternal death, and there were no injuries to the mother's soft parts that required repair. In other words, there were no tears of the cervix or the perineum that necessitated suturing. There were no alarming hemorrhages, and the period of involution in these cases was shorter than ordinary with less flow during the puerperium. The convalescence was more rapid due to the elimination of the shock that was experienced by patients going through a long second stage of labor. There was also apparent greater strength of the patient at the end of the puerperium. In reference to the fetus, there were 57 stillbirths, the greatest cause being prolapsed cord; in 30 cases alone death was due to this cause. His conclusions were as follows: "Version should be more often done to shorten the time of labor, lessen the shock to the mother, and eliminate undue pressure to the child's head. That the majority of occipito-posterior positions were best treated by version. That version can readily be accomplished in primiparae and should be more often done. That the fetal mortality in version should not be as great as in prolonged instrumental delivery. That head injuries to the child were lessened by a properly performed version."

Lymph Gland Extract, Its Preparation and Therapeutic Action.—Dr. DAVID HADDEN of Oakland, California, stated that he had used in several cases of streptococcemia the magnesium sulphate solution advocated by Harrower. The magnesium sulphate solution alone produced no leucocytosis, but used in conjunction with leucocytic extract, a marked leucocytosis resulted of a more profound character than the extract alone produced. These patients recovered. Two cases of easy bleeders, one with hemorrhage from the abdominal incision, the other with free oozing from the mucous membrane had a complete and permanent cessation of the bleeding almost immediately following the one dose.

His associates had been using this lymph gland extract in cases of hemophilia, pulmonary hemorrhage and tonsillar bleeding with very favorable results. He had used, during the last two years, lymph gland extract, in all inoperable cases of carcinoma, and discounting fully the possibilities of spontaneous improvement, he believed he was justified in the conclusion that the effects had warranted the use of the extract. He probably would never use body extracts in operable cases of malignancy as a substitution for operation, but if proven of value in animal work, they would have their place as a prophylactic. In inoperable cases, it gave one method that undoubtedly prolonged the patient's life and relieved many of the distressing symptoms, so that the amount of opiates necessary was lessened, but, above all, it put in our hands an ability to make the patients really feel something was being done for them. The present important field for the lymph gland extract was, however, undoubtedly in cases of hemorrhage and especially so in patients whose blood changes resulted in lowered coaguability. Dr. Archibald and Dr. Moore were anxious to see the extract tried out more extensively in tuberculosis and other chronic infections, for they felt that their laboratory experimental work had demonstrated its effect in these cases.

Dr. JAMES E. DAVIS of Detroit said he would like to ask Dr. Hadden if in using the lymphocytic extract he know how the platelets were produced. There were a number of theories about it. Some believed that the platelets had nothing whatever to do with the coagulation; others had raised the question as to just what the platelets were, whether they were fragmentary portions of the lymphocytes, and he wondered whether light had come to Dr. Hadden in this particular instance of the platelet.

Dr. HADDEN, in closing, said that, personally, he could not express any opinion with reference to the function of the blood platelets. We knew they were markedly increased, that so much of the spaces in between cells were filled with blood platelets. After a series of injections in lower animals Dr. Moore had proved conclusively, although he was not willing to give the evidence publicity, that we were dealing with an enzyme and the presence of the enzyme produced these changes.

Observations on Blood Pressures During Operations.—Dr. CHARLES W. MOOTS of Toledo, Ohio, said that, having made observations and records of the pressures in ninety-eight per cent. of his cases for the past eight years, he had, as a result of his experience alone, come to certain conclusions which he wished to offer at this time. (1) The systolic pressure alone was of very slight if any value. (2) The diastolic pressure alone was of much more value than the systolic alone. (3) The pressure ratio was the essential factor, and offered the earliest danger signal. (4) There were certain elements in technique which had marked and constant effect upon the pressures. These were as follows: (*a*) The physical or emotional state of the patient. (*b*) The position of the patient upon the table, the extreme Trendelenberg being the worst. (*c*) Overdosing by the anesthetist. (*d*) The amount of traumatism inflicted by the actual operation, such as cutting and tearing the tissues with scissors, the hands and other dull instruments; the packing of large gauze packs instead of rubber tissue into the abdominal cavity. (*e*) The preservation of the fluids in the body up to the hour of the operation, this being absolutely necessary to maintain the usual pressures.

Dr. R. R. HUGGINS of Pittsburgh said that when one was suspicious of any weakness on part of the circulatory apparatus of the patient, if he would take the pulse pressure with the patient in the lying position and found that it went down that patient was a bad risk. A patient with a blood pressure of 170 or 180, with low diastolic pressure, should always be watched. The same thing was true of low blood pressure.

Dr. CARSTENS said that he had for some time insisted on taking the blood pressure of patients a day or two before operation, and if we had a patient with a blood pressure of 170 it was dangerous to operate before adopting some measures to reduce it.

Points in the Diagnosis of Pelvic Troubles—Dr. J. HENRY CARSTENS of Detroit said that these patients had pains when moving the uterus and the pelvic organs in certain directions. If one pulled the uterus to the right, they complained of severe pain in the left side, and vice versa. When one pulled the uterus away from the bladder no complaint seemed to be made, but when one pulled the uterus forward or away from the rectum severe pain was complained of, often in the back. These cases were due to adhesions, and he believed the adhesions were caused by an infection from the rectum and sigmoid, as these patients were often suffering from chronic constipation. In many cases it was difficult to convince the patients that an operation was necessary when they had always been in perfect health before. He was convinced that when the history was perfectly clear of the non-existence of any trouble previously with a gradual onset of pain and distress, it was very much increased when moving the uterus and the pelvic organs.

Care of Patients Before and After Operation.—Dr. H. WELLINGTON YATES of Detroit stated that every surgeon should be a humanitarian. Surgery was a thing of art as well as science, a thing needing a fine esthetic sense rather than mere boldness. It was constructive, not destructive; it was saving life, not taking it, and likewise a surgeon was not he who had boldness, but one who had judgment, not alone he who knew how and when to operate, but also he who knew to refrain and when to conserve. Surgeons had paid too little attention to the internal secretions. Patients did not come for operations *per se*, they came to be cured of a malady of which they usually knew nothing, and placed themselves in our hand, because they had been referred to us by some other physician, who had failed to cure them. We should be exceedingly careful in the selection of such cases. As a rule, they were not given thorough examination—general physical examination. In general, he had been giving his patients more preoperative care than formerly. For two or three days he fed them well on easily digested nutritious foods; the last day he gave six ounces of water each hour while awake; this filled the blood-vessels, increased kidney, liver, and skin excretions and secretions. Nervousness and loss of sleep won exhausting and should be met by such remedies as the usual sedatives or opium. He thought it imperative that the patient be given sufficient quantities of opium to induce sleep. As regards obdominal surgery, we had learned that the viscera and their coverings spoke in no uncertain manner, and to some extent we had learned their language and, therefore, after an operation some of them cried out by expression of pain; some by way of abdominal distention; some by way of vomiting; some by thirst; some by pallid skin and sunken eyes; but the meaning of it all was, that we had given insult. One's insides were never intended to play ball in, but if perchance the ball had gotten in, our duty was to get it out as quickly as we could, with gentleness and safety. We had been taught by this language that we must get in and get out; that we must do the least handling possible to accomplish results; that we should avoid forcible retractions, and when we sought to pick up bleeding points, should pick them up separately, instead of insulting all the adjacent tissues; warm moist gauze, used gently, was less offensive than dry gauze, used roughly. The handling of patients should vary in accordance with their psychology and the nature and severity of the operation. In all operations of gravity, he used the Murphy drip, with bicarbonate of soda and glucose, as soon as the patient was returned to her bed. The soda would overcome tendency to acidosis, the glucose furnished an easily absorbable carbohydrate, and thus supplied energy. In those who through accident had lost much blood or who sweated profusely, the giving of two pints or more of this solution relieved the distress of extreme thirst and overcame the tendency to shock. In closing he wished to leave these thoughts: (1) Our patients were entitled to more preoperative and post-operative care than they had been receiving. (2) Patients suffered from shock in consequence of long anesthesias, exposures, and rough handling of tissues. (3) Surgery was a thing of art and gentleness as well as of knowledge and skill.

Fibromyomata Uteri and Cardiovascular Disease.—Dr. BEN R. MCCLELLAN of Xenia, Ohio, said that since attention had been directed to this interesting question, he had had opportunity to study carefully twenty-six cases of fibromyoma uteri, nine of which had well marked cardiovascular complications. In each case the diagnosis of the latter condition was confirmed by a competent internist. Of the nine, only two gave any history of other adequate cause than the presence of the fibroid uterus; these two gave distinct histories of a previous acute pelvic infection. Two of the nine patients died, one within a few hours following a difficult removal of a very large multiple fibroid of many years' growth, which had undergone cystic degenera-

tion, and was complicated by every extensive adhesions to the surrounding viscera. The heart behaved badly during the operation and death was undoubtedly due to shock, which in turn was caused by extreme traumatism in the presence of heart and blood vessels already handicapped by changes due to the presence of the chronic uterine disease. The other case, which had very pronounced cardiac and renal complications, was carefully prepared for the operation which was not difficult, although the tumor was of extreme size. The patient made an exceptionally good recovery up to the eleventh day, but died without warning while sleeping after a dinner which she had greatly enjoyed. No doubt the cause of death was brown atrophy of the heart. The remaining seven cases had all recovered with symptomatic relief from cardiac trouble, and only three, on careful examination, showed some hypertrophy. That a relationship between the two diseases existed there could scarcely be any doubt, but the etiology of the cardiovascular changes remained as yet in the field of theory.

Operative Judgment as a Factor in Surgical Mortality and Morbidity.—Dr. Roland E. Skeel of Cleveland, Ohio, said that in the matter of the particular operation which he performed he would cite two or three widely separated types of cases as examples. There might be an honest difference of opinion as to whether exophthalmic goiter was a medical or surgical condition, but there could be no honest difference of opinion as to the outcome of properly applied surgical treatment. Even this rarely gave a complete cure in the sense that all the symptoms were relieved permanently and at once, but it did convert the patient from an invalid or semi-invalid into one whose condition was such that self-support was possible and the health nearly as good as the average, but this result could not be obtained by slavishly following out one method of procedure whether that be pole ligation, tying of one or more vessels, or partial thyroidectomy. The last had a prohibitive mortality if used in each and every case, the first two were not efficient in the chronic slow-going type of cases, especially in women, while they not only had a very low mortality but a high permanent recovery rate in acute cases in the male, in whom the pelvic functions did not constantly disturb the nervous equilibrium. By a proper selection of cases for the various procedures, by a judicious selection of the anesthetic for the individual case, and, above all, by speed in operating, absolute prevention of postoperative bleeding, gentle manipulation of the gland, and sealing of the relatively large raw area by painting the wound surface with tannic acid solution combined with drainage, practically every case could be saved. In the treatment of *intestinal obstruction* the slavish obedience to some precept learned while a student or swallowed in its entirety because propounded by the master of a surgical clinic was likely to result in as serious a disaster as delayed diagnosis. To eventrate every patient through a huge incision meant that the operator had utterly overlooked the possibility of death from shock due to exposure of the peritoneum and much handling of the gut; to attempt operation through a wholly inadequate incision meant that an enterostomy only would be done. Reopening the primary incision in postoperative obstruction was all that was needed ordinarily, since the obstruction would be found in or about the operative site, and under any circumstances an incision large enough to admit the hand for exploration should be sufficient unless the obstruction was at a point far remote from the exploratory opening.

(To be continued.)

Insufficient Protection in Radiology. — Nogier questioned as to whether the customary protection really protects in deep radiation in which very hard tubes and very penetrating rays are employed and undertook a series of researches to decide the question. He found the apparatus guaranteed by manufacturers does not protect at all. A lead glass shield was found to be of unequal thickness and not opaque. Despite this shield a photographic plate exposed during a session of radiotheraphy was impressioned in an intense fashion. The rays which pass through the shield cause secondary rays when they impinge against the walls or other objects which also affect photographic plates, even behind protecting screens. Silk containing lead salts gives but feeble protection, and eight thicknesses are inferior to the leaded rubber of Müller.—*Archives d'electricité médicale.*

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held October 6, 1916.

Dr. John Douglas in the Chair.

Rupture of the Uterus with Prolapse of Intestines—Resection.—Dr. Seward Erdman presented this case. He stated that the patient was an Italian woman, 23 years of age, and married, who was admitted to Dr. Pool's service at the New York Hospital on June 5, 1916. Three months before admission to the hospital she became pregnant for the first time. One month before admission she began to bleed profusely, and had continued to bleed since that time. For the past two weeks she had had abdominal cramps. During curettement for incomplete abortion which was being performed under ether anesthesia and with asceptic precautions, the operator recognized the prolapse of intestine into the vagina and at once sent the patient to the hospital. The pulse and general condition of the patient were excellent. Immediate operation was performed. After iodine preparation, a median suprapubic incision was made. Upon opening the peritoneum, some four ounces of free blood were encountered. The soft, boggy uterus, the size of a three months' pregnancy, showed a linear tear one and one-half inches long in the fundus posteriorly, just medial to the right cornu and on a level with the tube. Firmly wedged into this rent were the two limbs of the loop of ileum, its mesentery crowding still more the small tear. With the gentlest traction, and without difficulty, the loop was drawn up out of the uterus, when it was found to consist of about fifteen inches of collapsed and badly traumatized ileum torn completely from its mesenteric attachment. The torn edge of the mesentery had been well puckered into the uterine wound and its vessels thrombosed so that it bled scarcely at all. Fifteen inches of the ileum were resected, a lateral anastomosis by suture using the Roosevelt clamp having been done. The wound in the uterus was closed by two layers of sutures. The abdominal wound was closed without drainage. With the patient in the lithotomy position a large blunt curette was passed lightly, bringing away several small fragments of membrane. On the third day both breasts became painfully distended with milk, requiring stuping and a tight binder. The wound healed by primary union and the patient went home on the twelfth day. The report from the Follow-Up System snowed that the patient developed a slight left saphenous thrombo-phlebitis soon after leaving the hospital, which troubled her for four weeks. She had suffered from no further abdominal, intestinal or pelvic symptoms.

Dr. Charles H. Peck said he had had a case similar to the one reported by Dr. Erdman some fourteen years ago in which eight and one-half feet of intestine was drawn through the rent in the uterus. As soon as the intestine was recognized laparotomy was performed by another surgeon and it was replaced but not resected. The intestine was stripped from the mesentery just as in Dr. Erdman's case. Twenty-four hours later, when the case came under his care, resection was performed and the patient recovered in spite of the presence of well-marked peritonitis. Dr. Peck said he had followed this case right along until a year or so ago, and she had remained well. He had been interested in the case because of the length of intestine removed, and had followed it to see what the results might be. No chronic diarrhea had developed. Some two years after this operation the patient had undergone an operation for ventral hernia, and it was interesting to see what was found at the site of the anastomosis. Everything had smoothed out and the ileum was practically free from all traces of operation.

Accidental Scalping United per Primam.—Dr. George Sheinberg presented this patient by invitation. He stated that the woman had been admitted to the Lincoln Hospital with a complete eversion of the scalp, the entire scalp resting on the occipital bone. She was employed in a laundry and her hair was caught in a shaft. She was not unconscious and grasped the scalp, and did not allow it to be torn off completely. The scalp was torn through the eyebrows just over the bridge of the nose and from ear to ear. The wound was full of loose hair and particles of dust. It was cleansed, sutured with three rows of deep sutures, and drainage was provided for in the back of the head. After the operation the patient's temperature never rose above 99.5° F. and she had no pain, headache or dizziness,

and she felt well. There were a few adhesions over the right eye.

Osteomyelitis in Children (Two Cases) with Demonstration of Lantern Slides of X-Ray Plates Showing the Bone Repair Following this Disease.—Dr. FREDERIC W. BANCROFT presented these patients. The first case occurred in a boy, 5 years of age, who was seen two days after having sustained a fall and injury to the left knee. The child had had chills and fever, but had not vomited. The knee was red, swollen, and exquisitely tender. Physical examination was negative save for enlarged and injected tonsils and a few palpable nodes in both cervical chains. The child complained of much pain and the antitibial region was particularly tender. Active and passive motion were limited. There was an abrasion one inch in length on the inner aspect of the knee. During a period of seven weeks the following operations were performed: (1) An incision carried through the fascia and periosteum through which four ounces of pus were evacuated. Counter drainage was established. (2) Incision and drainage of bilateral suppurative parotitis. (3) Incision and drainage of metastatic abscess of the back, with the evacuation of eleven ounces of pus. (4) Aspiration and irrigation of the knee joint, after which the knee was put up in entension. (5) Aspiration and irrigation of knee joint as before. (6) Excision of sequestrum of the tibia. An incision was made from the tibial tubercle on the anterior surface of the leg to about 5 cm. above the lower extremity of the tibia. A sequestrum about fifteen inches long consisting of the entire circumference of the bone was removed and a smaller sequestrum about 4 cm. in length was also removed at the lower portion. There was beginning involucrum at the lower end. The sequestrum extended up as far as the epiphysis. After removing dead bone and exuberant granulation tissue, a gauze packing was inserted at both extremities and the intervening area sutured together with deep silkworm gut, going through skin, muscles, and periosteum, and thus largely obliterating dead space. A small area was left for blood clot to form within the periosteum. The bacteriological examination showed the staphylococcus albus in cultures from the parititis, from the leg, and from the blood. In the culture from the leg there was also a member of the streptococcus group present. Nearly two months after the last operation and almost four months after the first, a sequestrectomy for chronic osteomyelitis of the tibia was performed. A cavity in the bone was found, about 1 x 2½ inches in size. Two sequestra were removed and considerable soft granulation tissue curetted away, care being taken not to destroy any healthy endosteum or connective tissue. After hemostasis was established, the cavity was filled with Mosettig Morehof's bone wax. Three days later the patient had a temperature of 103° F., and some of the bone wax was removed. About six weeks later an operation was performed for chronic osteomyelitis humerus. The bone was found diseased from about the middle of the shaft up to a short distance from the epiphyseal line. The deltoid fibers were separated; the bone was found not covered with periosteum, much roughened, and with two cloaca extending into the medullary cavity and small abscesses in the fiber of the deltoid. Cultures showed a pure growth of staphtlococcus aureus. This operation was performed on November 27, 1915. On June 19, 1916, another operation was done, consisting of an excision of a sinus that included a small sequestrum from osteomyelitis of the humerus. Convalescence was uneventful. The second patient was a girl, 8 years of age, who fell and injured her left knee. Her past history and physical examination were negative except for a few palpable lymph nodules in the left cervical chain. The knee appeared red and swollen and was extremely tender, active and passive motion at the knee joint being practically *nil*. The knee was soft and edematous, and a patellar click could be made out. There was likewise a swelling in the popliteal space, which looked and felt like a popliteal bursa. On May 11, 1915, incision and drainage for suppurative arthritis of the left knee was performed. In this case also there followed a series of operations including incision and drainage of the popliteal space, incision and drainage of a secondary abscess on the outer side of the thigh about four inches above the knee, drainage of an abscess under the extensor femoris on the outer surface of the femur, operation on the lower end of the femur at which the periosteum was found to be infiltrated and the outer side of the femur necrotic; at operation the wound in the lateral surface of the thigh was enlarged and about five cm. of the outer portion of the femur removed. The last operation was done on June 29. On October 16, a sequestrotomy for chronic osteomyelitis of the femur was performed. A cavity 1 x 2 inches in size was found in the bone, in the center of which were two sequestra. On December 14, an incision was made and drainage provided for an alveolar abscess and the right lower canine tooth was extracted. The patient was discharged on the 21st day and had since been under observation. Dr. Bancroft said he presented these cases not because he was attempting to show any originality of treatment, but to stimulate discussion so that they might derive some fixed ideas in regard to therapy. He discussed the following disputed points: (1) In the acute stage, how much drainage was necessary? Should one make a groove throughout the entire infected area, or was it sufficient to make numerous drill holes into the medullary canal to allow the pus to escape? (2) How soon after the acute process was it safe to remove the sequestrum? This latter question involved two classes of cases: (a) Those in which there was a second bone to act as a splint in the forearm or leg. (b) Where there was no other bone to act as a splint. After discussing these two classes of cases he concluded that in acute osteomyelitis an attempt should be made to produce sufficient drainage with the least possible trauma to the blood supply and tissues of the medullary canal. This could often be done by making good-sized perforations into the canal. The sequestrum should be removed as soon as sufficient involucrum had been formed to resist the pull of the muscles. In the tibia and fibula six weeks after the onset of the acute process might be sufficient. At this time the *x*-ray showed only a very small shadow of involucrum, about one-sixteenth of an inch. In the femur or humerus a longer time was necessary—Nichols thought about sixteen weeks.

Congenital Goiter.—Dr. EDWARD W. PETERSON presented a girl, twelve years of age. He stated that on January 18, 1905, when the patient was five weeks old, she was admitted to the Babies' Ward of the Post-Graduate Hospital. Her parents were Hungarians and both were healthy. There was no syphilis, tuberculosis, cancer, or goiter in the family. The mother had had one miscarriage at the second month. This was the first child. The labor was easy and uneventful. The infant was normal except for a relatively large tumor on the right side of the neck. There was some difficulty in breathing for the first two hours after birth, after which there was neither dyspnea nor dysphagia. Aside from the deformity, the tumor apparently produced no symptoms. The physical examination showed a growth on the right side of the neck, behind and to the inner side of the sternomastoid muscle, extending from the level of the jaw downward nearly to the clavicle. The tumor was made up of two masses, the larger situated above. It was smooth on the surface, of firm consistency, and did not fluctuate at any point. Below and to the side there was distinct palpable nodulation. An incision was made parallel to the border of the right sternoeleidomastoid muscle. A fibrous capsule which surrounded the growth was opened and the tumor was dissected out without difficulty. There was very little hemorrhage. Several times during the operation artificial respiration had to be resorted to. The wound was closed without drainage. For twenty-four hours after the operation the infant had to be prodded occasionally, as the breathing would stop. A nurse was in constant attendance and would do artificial respiration at such times. The temperature rose to 105° F. shortly after the operation and then gradually declined. There were no special features until the ninth day, when there occurred a convulsion lasting for five minutes. On the thirteenth day there was twitching of the extremities, and the eyes rolled from side to side. On the fourteenth day there were almost constant convulsive movements of the hands, arms, and legs, with twitching of the facial muscles and rolling of the eyes. It was about this time that the pathologist reported the specimen to be a "congenital thyroid tumor" (goiter). Believing from the appearance of the two lobes making up the growth, that the whole thyroid gland had been removed, thyroid extract was started at once, followed by a cessation of the tetany. At this time palpation of the neck revealed no evidence of any remaining thyroid tissue. The thyroid feeding was kept up for the first four years of the patient's life, and was then discontinued. A close watch was kept for

the appearance of any evidence of hypothyroidism, but the subsequent development of the patient mentally and physically had been normal. This was explained by the fact that for some time now it had been evident that all of the thyroid had not been removed at the operation. Palpation of the neck showed, to the left and attached to the trachea, what should and did correspond to the left lobe of the thyroid gland. Originally this could not be felt.

Pathological Report.—Dr. Sondern made the following report: Macroscopically, the tumor was horseshoe in shape; one side was composed of a large elongated tumor mass measuring 6 cm. in length, 4 cm. in width, 3 cm. in thickness. The other side was composed of a tumor measuring 4 cm. in length, 2½ cm. in width, and 2 cm. at its greatest thickness. These two tumors were joined at the concavity of the horseshoe by an isthmus of fibrous tissue. Both of the tumor masses had a slight irregular lobulated appearance. Microscopically, sections taken from both tumors showed the same structure, which was that of the thyroid gland. The acini had undergone a slight adenomatous proliferation and were filled with a very dense colloid material, the greater number of them being distended by it to the dimensions of small cysts. The epithelium was very much flattened by the intra-acinus pressure of the colloid. Nowhere did the epithelium show any malignant proliferation. The entire growth was surrounded by a thin fibrous capsule. The diagnosis was adenoma and colloid degeneration of the thyroid gland (goiter). The points of interest in this case were (1) the presence of a congenital tumor of the neck which proved to be a goiter; (2) the abnormal location of the thyroid gland; (3) the accidental complete thyroidectomy; (4) the development of tetany. (5) the disappearance of the tetany upon the administration of thyroid extract; (6) the subsequent normal physical and mental development of the patient. The following questions naturally arose: Was all the thyroid tissue removed at the time of the operation? Why did tetany develop? Would the child continue to develop?

Dr. Peterson also presented a second patient, a boy 10 years of age, from whom the thyroid had been removed without any great difficulty and who had been greatly improved since the operation.

Dr. Henry C. Falk presented a patient who had undergone a bilateral resection of the thyroid by the method which he described in his paper.

Exophthalmic Goiter.—Dr. John Douglas presented this case. He stated that he showed this patient not alone because the exophthalmic goiter was improved by operation but because of the apparent relation of hypothyroidism to dispituitarism in this case. The patient was first seen on November 6, 1915, when she gave a history of having been ill for six months. She had tachycardia, a pulse of 140, marked sweating, flushing on emotional excitement, exophthalmos, tremor, and attacks of vomiting. She was so sick with the hypothyroidism that it would have been dangerous to operate, so she was put to bed and treated for the condition. She had large extremities and the typical symptoms of dispituitarism. The sella turcica showed no enlargement by *x*-ray examination. Pituitary extract was given and the symptoms immediately became much worse; when it was discontinued they became better. In order to make sure that it was the pituitary extract that aggravated the symptoms, the drug was administered again, and again the symptoms became worse. As was well known, it had been proven that there was a relation between the adrenals and the thyroid, and indeed between all ductless glands, and a similar relation seemed to be demonstrated in this case. This case gave evidence of some slight degree of acromegaly. As the patient was still too ill to stand a hemithyroidectomy, an attempt was made to ligate the thyroid artery under a local anesthetic, but she became so excited and started vomiting, so the attempt was not successful. Gas and ether were then administered and a hemithyroidectomy was performed. Since the operation there had been a very marked improvement in the condition of the patient; the pulse was very little more rapid than normal, being about 80, instead of 140 as before the operation, and the patient had gained fifty pounds in weight.

A Case for Diagnosis.—Dr. Reginald H. Sayre presented this patient, a young man who had first come under his observation last June. He gave a history of having stubbed his toe and fallen down stairs three years before. A few weeks after this injury a swelling developed in his knee and the calf of his leg and he suffered a great deal of pain in the neighborhood of his knee. The question in this case was whether the condition was in any way connected with the bones or not, and whether it was a malignant condition or not. The mass had grown to its present size within a few months after the injury and had not enlarged materially since. He had at first thought that it might be an osteoma and had applied a bandage, but without results. There was a little mass in the femur and what this was he was not prepared to say. The soft mass seemed to be divided into two or three parts by trabeculae. Dr. Sayre said he was somewhat at a loss for a diagnosis and would be glad to receive suggestions.

Dr. Charles H. Peck said that about two years ago he had had a case with a tumor somewhat like the one exhibited by Dr. Sayre's patient. It was in the popliteal space and he had taken it to be some form of bursitis. The patient had practically no pain, though he had had the tumor for two years. He had consulted a number of surgeons during this time, who expressed different opinions regarding it. Dr. Peck said he thought it was a non-malignant condition and attempted to excise it. He found that it was a sarcoma and very difficult to remove. He dissected it out as best he could, but it returned later in a much more malignant form than the original growth. The growth in Dr. Sayre's case was in almost the identical locality, but in this case he did not believe it was a sarcoma.

Dr. George H. Semken said he had had a patient with a condition somewhat similar to that presented by Dr. Sayre. There was a mass in the gastrocnemius which was diagnosed as a chronic bursitis. It was removed and sent to the laboratory and the report stated that the growth was largely cartilaginous. This growth extended up to the popliteal muscle where it was attacked. Dr. Semken said it was not uncommon to get such cartilaginous growths in old injuries and he offered this as a possibility in the present case.

Dr. Robert T. Morris said he did not see why Dr. Sayre hesitated to do an exploratory operation. The growth might be a myoma and it might respond to *x*-ray treatment. He knew of two cases in which there was sarcoma in this region in which the growth had been kept under control by the *x*-ray. In this case he would suggest getting a specimen.

Dr. Alfred Stillman said that he had had a case with a somewhat similar tumor, which was soft and nodular. He was doubtful as to the diagnosis, but took it out and found it was a myxoma; he was inclined to think that this was a myxoma.

Dr. W. S. Schley thought the growth might be a fibromyoma.

Dr. Sayre said he was much obliged for the suggestions and possibly the patient might decide to be operated on, but thus far he had refused.

Resection of the Thyroid.—Dr. Eugene H. Pool presented this paper, which was read by Dr. Henry C. Falk. He stated that partial thyroidectomy as usually practised consisted in extirpation of one lobe and isthmus, sometimes supplemented by resection of part of the second lobe. In the removal of the lobe the technique generally followed was an intracapsular extirpation. In order to afford a greater degree of protection to the recurrent laryngeal nerve and to the parathyroids some surgeons advocated leaving a layer of thyroid tissue in this region; but this procedure resulted in more hemorrhage, prolonged the operation, sometimes difficult to control, and led to greater postoperative exudate. In a former article Dr. Pool had presented an anatomical study to determine whether the theoretical advantages of leaving a portion of the posterior part of the lobe had sufficient anatomical basis to outweigh the practical disadvantages. From this study he concluded that for the prevention of tetany the posterior part of one lateral lobe must always be left. Even if one lobe only was operated upon, permanent safety was best insured by leaving *in situ* the posterior part of that lobe. Then, if s a subsequent operation with complete removal of the second lobe became necessary, the operation might be performed with relative safety. He found that the recurrent nerve was relatively immune from injury when a true intracapsular extirpation of the lobe as made, yet there was some danger of injuring it which might be avoided by leaving a portion of the posterior part of the lobe. He found further that it was an advantage to leave *in situ* the posterior part of both lateral lobes, in relation with each of which a recurrent laryngeal nerve and two

parathyroids usually lay. The amount of thyroid that must be left in a thyroidectomy to avoid myxodema was variously estimated as from one-sixth to one-fourth of the gland. The case sto which this operation were applicable were in general the diffuse colloid goiters; it was not necessary, of course, in the single cystic thyroid or adenoma. It had a very limited field in the exophthalmic group where symmetry was a secondary consideration and the patient was operated upon for symptoms only. In regard to the theoretical objections to resection, it might be stated that hemorrhage could be controlled either by Balfour's technic or by use of the clamp described in this paper. After describing Balfour's method of bilateral resection employed at the Mayo Clinic, Dr. Falk presented the clamps, similar to a Scudder gastric clamp, which facilitated the technic of resection by lifting and steadying the lobe and controlling hemorrhage. The lobe was freed with or without ligation and section of the superior vessels as the case demanded; the isthmus was cut across and its stump separated from the trachea; the lobe was then grapsed well back by the clamp, which was placed vertically with one blade on each side of the lobe. The clamp had long, delicate blades so as to grip but not crush the thyroid; it had a broad clutch by means of which it might be locked while the blades were comparatively far apart as in grasping a broad lobe; the bayonet shape allowed the blades to be introduced more readily into the wound. The technic of the operation was described in detail and illustrated by lantern-slides. With the patient in the oblique position, the head higher than the feet, a sand bag under the shoulders to extend the neck, and the goiter frame in place, intratracheal anesthesia was administered with the Janewey apparatus. A curved incision was made corresponding to the crease of the neck from the external jugular of one side to that of the other side. The anterior jugular was clamped, cut, and ligated. The deep fascia cut through to the infrahyoid and sternomastoid muscles. The flap of skin, platysma, and deep fascia were freed with the knife and lifted as far as the incisure of the thyroid cartilage. The separation of such a flap was easy because of the natural cleavage plane. The point to be emphasized was that at the anterior edge of the sternomastoid the division of the fascia which pasesd behind this muscle must be cut as the flap was lifted. The depressors of the hyoid were separated vertically with the scissors passed between the sternohyoid muscles. In general the sternohyoid, sternothyroid, and omohyoid should be cut across and reflected on one or both sides. The line of division of the muscles should be high so as to avoid their nerve supply. Straight clamps of the Pean variety were placed transversely across the muscles which were to be severed. The cutting of the muscles involved a confusing detail in that the sternothyroid was extremely thin and it might be left undivided. With care, however, all the muscles might be severed together. The handle of the lower clamp was slowly rotated and the muscles as a sheet were easily stripped free. The lobe, with the large veins and capsule, now presented, and by passing the finger gently into the plane mesial to the carotid and keeping away from the capsule, this tissue plane was opened up. The left index finger was introduced behind the upper pole of the lobe, making the superior vessels accessible for ligation. These were ligated high up. The lobe was then lifted forward and mesially and separated from the posterior tissues until the inferior thyroid branches were reached. It was then allowed to drop back. The pyramidal lobe was dissected free and two clamps were placed across the isthmus and the isthmus cut across between. The right portion of the isthmus was freed from the trachea. The lobe, with the pyramidal lobe and stump of the isthmus, was then lifted and the goiter clamp placed from above downward and closed so as to grasp gently the posterior part of the lobe anterior to the recurrent laryngeal nerve and the parathyroids. The lobe was thus steadied and sufficient pressure was exerted to control hemorrhage. Large vessels on the surface were clamped behind the proposed line of resection and the anterior part of the lobe excised. After ligating bleeding vessels the sides of the lobe were then approximated with mattress sutures and the edge overhanded with a continuous catgut stitch. A small lobe was thus constructed without injury to the recurrent laryngeal nerve, the parathyroids, or the inferior thyroid artery before its entrance to the gland. The left side was treated in the same manner, two small lateral lobes being thus substituted for the enlarged thyroid. A puncture wound for drainage was made about an inch below the skin incision. After removing the sand bags so as to relax the muscles, the depressor muscles were approximated by a stitch which overhanded the two clamps holding their cut edges. The clamps were then removed and the stitches drawn tight and tied. This operation relieved pressure, minimized danger to parathyroids and recurrent laryngeal nerve, provided a sufficiency of thyroid tissue, and insured symmetry. Double resection might be carried out readily either by Balfour's method or by the use of the clamp described, or by a combination of the two methods.

Dr. CHARLES H. PECK said that the technique which Dr. Falk had described was a very rational one and had distinct advantages over hemithyroidectomy in simple colloid goiter. It was necessary to leave some tissue, and if one left it all on one side he was likely to have disappointing results. If this plan was carried out and a fair amount of tissue was left there would not be so many cases that would require a second operation. Dr. Peck said he had been doing bilateral resection for some time, which he preferred to a hemithyroidectomy, but he thought the method just described was the best he had seen; he had not as yet used these clamps, but intended to do so.

Dr. JOHN DOUGLAS said that he had done the bilateral wedge-shaped resection and the hemorrhage had been considerably less than he had expected. There had not been a great deal of bleeding from the thyroid itself, but he had found it necessary to drain his wounds, as they bleed freely afterward, and unless the drainage was very efficient one might have had bad results.

Dr. HORACE M. HICKS of Amsterdam, N. Y., said that he had been interested in Dr. Pool's paper and his very clear and able description of his technique. He himself had operated on over 200 goiters, and though this was few in comparison with the number removed by Kocher or Charles Mayo, still it had been quite an experience, an experience that had been sometimes tragic, oftentimes commonplace. In most instances he had been able to remove the gland without trouble. He had used the "bow" or "half moon" incision. The lowest point in this incision was carried within three-quarters of an inch of the clavicle. The skin was then dissected as high as the upper extremities of the incision would permit. At a point corresponding to about the middle of the gland, the external jugulars were located and each tied twice at an interval of about one-half an inch. The muscles were then divided, without clamping, between the ligatures before mentioned, from one sternomastoid to the other, clean through to the capsule of the gland. He had next endeavored to reach the upper end of either side, which was most desirable, though not always practical; if unable to do this easily, he had tied the superior thyroidal artery as high as possible and cut clean through the gland at this point, suturing or clamping bleeding points. From this stage a fairly rapid gauze dissection carried one to the trachea, being careful to keep next to the capsule but not tearing or wounding it. The method was much like the removal of the sac of a hydrocele. After very carefully securing the superior thyroid arteries by ligatures, a scissor dissection was used to complete the removal of the gland from the trachea. No clamps were used for fear they might include within the grasp the recurrent laryngeal nerve.

Disinfection of War Wounds by the Carrel Method as Carried Out in an Ambulance at the Front.—Dr. H. H. M. LYLE read this paper which was illustrated by colored photographs (Lumière) showing the wounds and their progress. The Carrel method of disinfecting wounds was based on the following conception: To render an infected wound sterile it was necessary to employ a suitable antiseptic in such a manner that the chosen antiseptic came in contact with every portion of the wound; that the antiseptic be maintained in a suitable concentration throughout the entire wound, and that this constant strength be maintained for a prolonged period. If these conditions were fulfilled every wound would show its response to the treatment by the diminution and disappearance of its microorganisms. The antiseptic employed was Dakin's hypochlorite of soda, 0.5 per cent. This was an ideal wound antiseptic of high bacterial activity and low toxic or irritating quality. In addition to being a strong wound bactericide, Dakin's solution had, due to its pyo-cyto-hemolytic powers, the great clinical advantage of being able to dissolve pus, old blood clots, tissue débris, etc. The living tissues resisted this dissolution, due to the protection afforded them by the sodium chloride of the

serum. The course of the wound was directly dependent on the thoroughness of the first surgical act and this should be carried out under the strictest aseptic precautions and at the earliest possible moment. This consisted of a thorough, methodical, mechanical disinfection of the wound with the extraction of all shell fragments; particles of clothing, dirt, etc. The operative field was painted with the tincture of iodine, the bruised and necrotic edges of the skin were trimmed away with a sharp knife, and everything that could have been infected by the traumatism, or could have become the source of infection, was removed. Gentleness of manipulation was the keystone of the technique. In many of the cases it would be found that fibers of clothing, grass, dirt, etc., were encrusted in the muscular surfaces of the wounds. To avoid overlooking this blood-stained débris the tract of the projectile must be lightly but methodically resected. Dakin's solution had, due to its hemolytic properties, the power of dissolving recent blood clots. A poor hemostasis invited the danger of a secondary hemorrhage. In the introduction of the instillation tubes, the guiding principle was to place them so that the liquid would come in contact with every portion of the wound. Instillations of the fluid were made every two hours by releasing the adjustable clamp controlling the flow. This interrupted instillation was kept up until the wound was proven sterile; the tubes were then removed and a compress moistened with Dakin's solution was applied. The Carrel method was not a continuous irrigation but a mechanical attempt to deliver an antiseptic of a definite chemical concentration to every portion of a surgically prepared wound and to insure its constant contact for a prolonged period. When on three successive days, the bacteriological control showed the wound to be sterile, it was closed by careful layer sutures. The wounds treated by the Carrel technique were entirely different in appearance from those treated by the ordinary methods. The Carrel wounds had strikingly bright red, vivacious granulations, a minimum amount of mucoid-looking secretion, and no odor. There was no redness, no tenderness, no induration of the skin edges. Under the light of the results obtained, many of the phenomena which they had been taught to consider as normal processes of wound healing must now be considered abnormal. The results obtained by the Carrel method in their ambulance were truly remarkable, and had to be seen in order to be appreciated. No secondary abscesses developed on the surface and there was only one case of osteomyelitis and this responded readily to treatment. The average stay for wounds of the soft parts was 14 days, for compound fracture 28 to 36 days. The transformation which was established in their results was startling, the immediate complications became more and more rare, and suppuration disappeared from their services almost completely.

Dr. Fred Albee said that while in France he had had a rather exceptional opportunity of observing the treatment of war wounds and could confirm everything that Dr. Lyle had said. Certainly the management of fractures and wounds in Dr. Lyle's hospital was excellent. Dr. Carrel's management of fractures was not up to Dr. Lyle's. The pictures had shown the condition of the wounds and he had never seen anything like the way in which wounds healed when sterilized by the Carrel-Dakin method. They were remarkable because of their lack of discharge and lack of sensitiveness, and because of their redness and suppleness and the ease with which they could be closed up. This bleaching powder had sometimes been wrongly used and a few hospitals had objected to it on the ground that it caused bleeding of the granulations. It must be remembered that the commercial bleaching powder was not pure and if it contained sodium hydroxide it would then cause bleeding. This difficulty was being remedied. At Dr. Blake's hospital they had carried out experiments in the laboratory to determine the potency of this antiseptic and the results of these experiments had been misleading. If the results of test tube experiments were not in harmony with practical results in this matter, then in this instance the test tube was not reliable. It had been objected that in wounds treated in this way pus organisms grew more luxuriantly in the lesions. It was found that if with a platinum loop some secretion was taken from a lesion and smeared on a slide, then dried and stained, many bacteria could be counted in an oil immersion. The wound should not be closed while one found bacteria in this way, but when the number of bacteria had diminished to one or two on a slide the wound might be closed with safety. It was generally recognized that mere observation of a wound was not a safe criterion by which to be guided in reference to the time when a wound might be closed witih safety.

Therapeutic Hints.

Treatment of Furunculosis.—This is both operative and medical and is followed according to the method of Unna: The operator first notes the set of the hair around which the boil is situated; then the skin covering the boil is gently squeezed until a bloodless white area is presented, which is the bacterial focus. With a darning needle sterilized to dull red heat this central white area is punctured to 3 or 4 m.m. in depth, care being taken to follow the direction of the hair. This plan of procedure immediately removes the focal area and gives instant relief of tension and pain. If such is not the result the operation has not been performed correctly. Any one of the following pastes may be used as a dressing:

℞ Kaolin (Fuller's earth), 20
Glycerin, 10
Ichthyol, 5

After this has been applied the surface should be covered with some impervious material such as guttapercha paper. Another paste which hastens healing is:

℞ Sulphur, 10
Oxide of zinc, 10
Chalk, 10
Glycerin, 30.

When no inflammation or irritation of skin is present the formula may be changed to: 10 parts each of sulphur, oxide of zinc, chalk, oil of turpentine, and vaseline. Axillary boils, while not as painful as those around the back of the neck, are more troublesome on account of the tendency to return. Unna states that in the beginning stages these abscesses may be opened with a small cautery, but that later the skin in the axillary region should be shaved and each small abscess opened by tiny incisions, after which the armpit should be dressed with

℞ Mercurial ointment, 25
Oil of turpentine, 5
Lead plaster, 20

This again should be covered with guttapercha paper, which remains *in situ* without any bandage. —*Berliner klinische Wochenschrift.*

Chronic Granular Pharyngitis.—Coble uses in this condition, especially when there is much irritation of the membrane, compound tincture of benzoin, full strength, applied to the membrane. Compound tincture of benzoin may be used effectively on gauze where a packing that will prevent foul odors is needed for the nose. Tincture of iodine, one drachm, glycerin one ounce, may also be applied to the nose and pharynx. The weaker solution should be used first, but if a stronger one be required the following prescription covers the need:

℞ Iodine crystals., grs. ijss-x
Potassium iodide, grs. vijss-xxx
Glycerin, ℥j

These iodine solutions are very efficacious when used after tonsillectomy and do not produce the pain caused by the application of some other solutions, such as silver nitrate, etc.—*Indianapolis Medical Journal.*

ACUTE POLIOMYELITIS.

BY H. L. ABRAMSON, M.D.,

NEW YORK,

BUREAU OF LABORATORIES, DEPARTMENT OF HEALTH.

ACUTE poliomyelitis, or infantile paralysis, as it is more commonly known, was first mentioned by Underwood at the end of the eighteenth century, but it was not clearly differentiated from other cerebrospinal disorders until 1840 by Heine. It was not until Medin reported his observations on the Stockholm epidemic of 1887 that the haze which enveloped the clinical aspects of this disease was somewhat lifted. He recognized and described in addition to the already familiar spinal form, from which it received its name, bulbar, polyneuritic, ataxic, and encephalitic types.

To the Scandinavian physicians belongs the large credit for the intensive study of the clinical, pathological, and epidemiological sides of the problem of poliomyelitis. Ample opportunity for such study was presented by the recurrence of epidemics in that country every six to eight years. The first to have been described was by Bergenholtz in 1881. Then Medin reported the epidemics of 1887 and 1895. Wickman,[1] also a Scandinavian, has contributed more clinical, pathological and epidemicological facts to the solution of the problem than any other man of recent years. He studied and reported the Swedish epidemic of 1905. It was he who first called attention to the abortive and meningitic types and a type resembling a Landry's paralysis. It was Wickman who first proved that the disease spreads from person to person.

The New York epidemic of 1907 to 1909 stimulated study of this disease. Very little, however, was added to the clinical side as a result of such study. The research turned to the rather mysterious questions of specific cause, problems of natural and artificial immunity, serum treatment. These studies which had their inception in the epidemic of 1907-1909 have received a tremendous stimulus by the epidemic now raging throughout the Middle Atlantic States. Scientific men of the big laboratories throughout the country are concentrating on the problems of detection of carriers; the recognition of the mild atypical cases; the production of a curative serum; problems of transmission, and most important of all, a protective vaccine. With the glorious record of past achievements in preventive medicine to encourage, I feel that the many minds now at work on these problems are sure to produce something that will prevent the recurrence of the dread scourge and render it as infrequent as smallpox is to-day.

Acute poliomyelitis has been conceded by all modern workers on the subject to be an acute general infection with apparently a special predilection for the central nervous system. It can be compared to measles or scarlet fever, each of which is an acute general infection with skin manifestations. The virus of poliomyelitis has a special affinity for nerve tissue in much the same way as the virus of rabies, the characteristics of which it greatly resembles. That this virus does attach itself to the central nervous system has been proven many hundreds of times in experimental work. The brain and cord of fatal human cases when injected subdurally into monkeys will produce after an incubation period of from 2 to 19 days a type of paralysis closely resembling the human type. This virus can be transmitted from monkey to monkey for many generations and this method of passage tends to fix the incubation period of monkey poliomyelitis, so that after a number of passages, the incubation period will be from 9 to 14 days.

The virus of poliomyelitis has been found elsewhere in the body. It has been demonstrated in the nose, mouth, and throat, and also in the mucous membranes of the intestines. It has been recovered from the blood in monkey poliomyelitis. The mucous membranes may be the points of entry for the virus, but it has been definitely proved that the virus is also excreted onto these membranes.

How the virus reaches the central nervous system is a much mooted question. Some believe that it is a blood infection and the virus gains entrance by that route. Others think that it makes its way into the brain and cord along the lymphatics of the nerve trunks. Against the former hypothesis stands the fact that the virus has not been demonstrated in the blood of human cases even in the earliest stages, though it has been found in the blood of one monkey that had been infected by the intracerebral route by Clark, Fraser and Amoss.[2] This last fact does not prove that it is a blood borne infection as it is possible to conceive of the virus being eliminated in that way and so reaching the mucous membranes.

That the virus gains access to the central nervous system by way of the perineural lymph channels is indicated by a rather conclusive experiment. Active virus was injected into the sheath of the sciatic nerve. Proximal to the site of injection, the nerve was ligated. This monkey did not come down with the disease, whereas the control animal whose nerve was not ligated showed typical symptoms in the usual period of time.

Other evidence which lends belief to this method of invasion of the central nervous system lies in the fact that that limb which receives an intramuscular injection of active virus is invariably the first to show symptoms, indicating that the virus is conveyed by the nerve of that limb. If it were primarily a blood invasion, it would be expected that occasionally another limb or limbs would show signs first.

Further, the perineural lymphatic route in poliomyelitis would fall into line with the already definitely established paths of infection of nerve-cell poisons, such as rabies and tetanus. So in view of the preponderating mass of evidence, it has become generally accepted that the virus gains access to the central nervous system by the perineural lymph channels.

As stated above, the virus of poliomyelitis resembles very much that of rabies. It is a nerve-cell poison; is filterable, that is, when an emulsion of the infected brain and cord is pushed through the finest grained porcelain filter, the filtrate retains the ability to produce infection in monkeys. This is unlike the common bacteria which are easily strained out by even coarser grained filters, the filtrate of which will contain no bacteria.

It is very resistant. It can stand a freezing temperature for at least 50 days; but is killed at 50° C. in ½ hour. It withstands the immersion in 50 per cent glycerin for long periods of time. It withstands drying much longer than fixed rabies virus. It is resistant to 0.5 per cent carbolic acid for 3 days. It is killed by 1½ per cent carbolic acid in 24 hours.

Pathology.—The pathologic changes produced by this virus are not striking when viewed with naked eye. The changes, such as they are, are to be found principally in the central nervous system as is to be expected when one considers the symptomatology of the disease.

The gross changes in the brain, basal ganglia, and pons consist principally of marked engorgement of the pial and parenchymatous vessels; an accumulation of an excess of serous fluid in and beneath the pia; edema of nerve tissue itself. In a rare case, where the involvement of the brain has been marked, as in the cerebral spastic types, one may find areas of softening of the cortex. I found one such case in an autopsy on a young man of 27 years, who presented what appeared to be a left sided spastic ehmiplegia. In this case a large area of the central and parietal portion of the cortex of the right side was softened into a mass of mushy consistency. There were signs of capillary hemorrhage, but no gross hemorrhage.

The changes in the spinal cords of most of the 35 post mortems done by the writer at the Willard-Parker Hospital in New York were those already described by Wickman, Harbitz and Scheel, and many other students of the pathology of this disease. They consist chiefly of a marked hyperemia and swelling of the gray matter. Whereas in a healthy cord of an infant, the gray matter is only slightly differentiated from the enveloping white matter, in the polio-infected cord, one finds the gray columns very distinctly marked off from the surrounding white matter. There is swelling in most cases of the anterior horns, though in some the posterior horns share in the process to an equal degree. The gray matter presents in the acute stage a distinct reddish tinge, in most cases, indicating increased vascularity. In some instances there are what appear to be minute circumscribed hemorrhages.

The white matter also shows congestion of its vessels, and in some cases marked edema, so marked at times as to produce a distinct softening of the cord. The posterior root ganglia show changes similar to that of the gray matter of the cord.

The remaining organs, as a rule, show little of import. Practically all cases terminating with respiratory paralysis show edema and congestion of lower lobes of lungs. The liver and kidneys often show marked congestion and frequently some acute parenchymatous degeneration. The spleen in a number of cases shows enlargement, congestion and a marked hyperplasia of the lymphoid follicles. The Peyer's patches in a few cases appear somewhat raised and reddened and the corresponding mesenteric lymph nodes slightly enlarged and congested. Otherwise there is nothing worthy of remark.

The microscope shows, in the affected portions of the central nervous system, marked congestion of the blood-vessels, with great accumulations of small round cells about them. Nerve cells can be seen in all stages of degeneration and in the process of being taken up by the phagacytic cells. There is an accumulation of excess of fluid which tends to separate the interstitial tissues. This is the microscopic picture of the stage of destruction. That of the period of reparation consists in the replacing of the destroyed nerve tissue by young connective tissue. This, as it grows older, contracts into firm fibrous tissue and produces the scarring of the gray matter, which is characteristic of the cords of recovered cases of poliomyelitis, in which there are residual paralyses.

The pathogenesis of this disease is still an open question among pathologists. Some think that the virus has a direct destructive effect on the nerve cell and that the vascularity, edema, and round cell infiltration are only the evidences of the body reaction to the presence of the virus. Another school of workers consider the nerve cell degeneration secondary to the marked inflammatory reaction; in other words, that the nerve cell is destroyed in a mechanical way by the effect of pressure of the engorged vessels, edema, and cellular infiltration.

The opinion of the writer coincides with those who consider the virus a specific nerve cell poison in a manner analogous to the virus of rabies, tetanus, and diphtheria. If one concedes that polio-infection is principally manifested by disease of the central nervous system, and there is no divided opinion on that score, then one must also concede that it is the active elements of the brain and cord, namely, the nerve cells, which have special affinity for the virus of poliomyelitis.

The epidemiology of poliomyelitis has not as yet been completely worked out. Much remains to be accomplished in this field of work. Wickman, however, by his celebrated work in the Swedish epidemic of 1905, has definitely proved that the disease is transmitted from person to person. He was able to trace units from one focus to another, and of the formation of foci from these single units along the paths of most frequent human travel, so that on the completion of his study, he was able to present a map showing the main central focus, with arms radiating along the most commonly used roads to other foci and these in turn exhibited similar arms extending into smaller groups of cases along the roads leading from this focus. It was, therefore, clearly demonstrated that one must watch the human animal in order to elucidate the finer point in the transmission of the disease. The question of how it is transmitted from one to another is as yet not solved.

Dr. M. J. Rosenau,[4] of Harvard, a few years ago thought he demonstrated that the virus was carried from one to another through the biting stable fly, much after the manner of malaria and yellow fever transmission by the mosquito. This work gained

considerable credence until it was definitely proved by Dr. Edw. Francis,[5] of the U. S. P. H., by a series of conclusive experiments that the biting fly was unable to convey polio-infection from one to another. That work has apparently settled the theory of transmission by that route.

The theory of transmission by dirt and dust obtained some basis through the work of Neustadter and Thro,[6] who demonstrated the presence of the virus in the dust of a room in which was isolated a case of poliomyelitis. Up to the present time this work has not been confirmed. While it is true that the disease is very prevalent in our congested East Side and South Brooklyn, it is also found in the outlying districts, where there is anything but congestion. It is found in the most sanitary homes as well as the filthy ones. So it seems to the writer that if dirt and dust were among the chief means of conveyance of the disease, it would be found almost exclusively in the very poor districts. That the virus may be demonstrated in the dust of rooms in which poliomyelitis cases have been cared for is no real argument for the transmission of the disease by that method.

The idea as to the causation of epidemics, prevalent in New York and shared by the writer, is as follows: The virus of a previous epidemic, having lost its virulence by means of burning itself out, has become quite widely disseminated onto persons who are or have become immune. This virus in the course of eight or ten years, through some unknown agency, receives an intensification of its virulence. In the meanwhile a crop of non-immunes has developed. Increased virulence of virus plus numbers of non-immune children equals an outbreak. This, to my mind, will explain the peculiar recurrence of the disease at intervals of eight or ten years, and will explain the almost simultaneous development of groups of cases at widely separated localities, as New York and Minnesota. It will also explain why in some epidemics there is a mortality of only 5 per cent. and in others of over 20 per cent. It is simply a matter of virulence. In one the virulence jumped four times as high as in the other. That the virus is present between epidemics is evidenced by the presence of sporadic cases. Twenty to thirty cases every year are seen by the Meningitis Division of the New York Board of Health. The mortality among these is very low, probably not more than 1 or 2 per cent.

Now that we have our outbreak started, how does it spread? It spreads despite all the efforts of modern hygiene and sanitation. There must be a reason, and that reason in our opinion is the fact that there is a form of the disease so mild that it is not recognizable by the rank and file of physicians. This type of case after a day or two of indisposition, with perhaps a little vomiting and fever, is up and about and playing with the neighboring children. This is one of the chief, if not the chief, means of the rapid spread of epidemics. Another means which will be difficult to rule out—and, in fact, observations in the present make it seem likely—is the carrying of infection into the homes by healthy adults.

To summarize our ideas of the building up of epidemics, we have, first, the man-to-man conveyance, the presence of a virus of increased virulence, the existence of a crop of non-immunes, the existence of a very mild type of the disease difficult of recognition and therefore not quarantined, and, lastly, the transmission by healthy adults.

Clinical Viewpoint.—From the clinical viewpoint, acute poliomyelitis is often simple, many times difficult, and nearly always terrible. In the present epidemic our mortality is about 22 per cent. of those cases recognized as poliomyelitis. If all the cases that were not diagnosed were included, it is felt that this percentage would suffer quite a loss. Previous epidemics in this country and abroad had a mortality figure of about 5 to 10 per cent. Seventy to eighty per cent. of those paralyzed have some residual paralysis.

The age incidence in some 2700 cases collected by Wickman is as follows: Up to 3 years, 39 per cent.; 3-6 years, 24; 6-9 years, 13; 9-12 years, 7; 12-15 years, 6; over 15 years, 11 per cent.

Leegaard presents the following figures in 788 cases: Up to 4 years, 28 per cent.; 5-9 years, 27; 10-14 years, 19; over 15 years, 26 per cent.

The age incidence in the mortality figures of the present epidemic in New York City up to and including July 31, 1916, in a total of 848 cases, is as follows: Under 1 year, 15 per cent.; 1 year, 23; 2 years, 20; 3 years, 14; 4 years, 8; total under 5 years, 80 per cent.; 5-9 years, 16.5; 10-14 years, 2; 14-35 years, 1.5 per cent.

From Wickman and Leegaard's[7] figures it is readily seen that while acute poliomyelitis is preferably a disease of early childhood, it will also attack young adults in considerable numbers. In my series of thirty-five post-mortems in the present epidemic there is included a case of 15 years of age, one 22 years, one 27 years, one 34 years, and one 58 years. When the figures on the age incidence are collated it would not be surprising if there were from 3 to 5 per cent. of cases over 15 years of age. The mortality figures of the New York Department of Health show a great preponderance of fatalities in children under 5 years of age.

Age appears to be the chief predisposing cause. Physical condition and character of surroundings play little part, if any, except such condition as congestion, which will, of course, permit more intimate contact of carrier of contagion, and the non-immune. The meteorological conditions cannot be blamed. The 1907 epidemic raged in a dry, hot summer. This epidemic holds forth in a rather moist, moderate summer. One of the worst epidemics in Sweden occurred in the midst of one of their very severe winters.

The clinical picture of acute poliomyelitis is that of an acute infection plus such manifestations of disturbance of the central nervous system as may have been attacked by the disease process. Thus we usually have a sudden onset, with fever of, say, 102° to 105°, headache, drowsiness, or irritability. The skin may be hypersensitive to touch so that the patient will cry out with pain on being handled; he prefers to be let alone. He may perspire excessively. Then he will complain of pain in the back of the neck, especially if moved. If an attempt is made to manipulate his legs, after the manner of Kernig, he will complain bitterly of pain along the spine and resist the efforts to straighten out his leg when it is flexed at the thigh. His knee jerks may be present, sluggish, or completely absent. The next day the neck may be more rigid, the Kernig sign more marked; if the knee jerks had been present they may have disappeared, with perhaps evidences of weakness in one leg or perhaps both legs.

If there is further progress of the disease up the cord, the next center struck after the arm center is that of respiration. That, in the great majority of

the cases, proves fatal, though there have been a number of instances in this epidemic where children have recovered after the respiratory center has been involved.

The description above presented is that of the common spinal type, and it is from this that the disease receives its name. It is the rapidly ascending form with respiratory involvement, the Landry type, which swells our mortality lists. If poliomyelitis were as simple as above described, the disease would present no difficulties to the physician. When one considers the multiplicity of physiological functions of the central nervous system, then, and then only, can one gain a true conception of possibilities of clinical manifestation of the disturbance of these functions. The virus may attack any portion of the central nervous system or several widely different portions at the same time. This fact gives rise to most bizarre forms of paralysis. It is this fact, too, which contributes so greatly to difficulty of an adequate classification of types.

Wickman classifies the types as follows: (1) The spinal poliomyelitis form, (2) the form resembling Landry's paralysis, (3) the bulbopontine, (4) the encephalitic, (5) the ataxic, (6) the polyneuritic, (7) the meningitic, (8) the abortive.

Other authors, as Zappert and P. Krause, give equally cumbersome classification. It is really very difficult to arrive at a compact yet comprehensive classification.

We prefer to classify the various types according to a classification already existing for separation of various chronic forms of nervous disease:

1. Cortical, where the upper motor neuron only is involved.
2. Spinal, where the lower motor neuron is involved; this is to include the bulbar paralysis as well as that of the cranial nerves.
3. Corticospinal, where both upper and lower motor neurons are involved.
4. Ataxic, when any of the systems which have to do with maintenance of a state of equilibrium are attacked, such as the cerebellum, posterior root ganglia, the vestibular nerve.
5. The meningitic form.
6. The abortive or non-paralytic form.

The clinical manifestation of the cortical type may be paralysis of spastic type; some present clonic convulsions on one or both sides, continuing in some instances as long as forty-eight hours. This type has not been a frequent find in this epidemic.

The spinal form is the most common type, and presents the flaccid type of paralysis with loss of reflexes. The corticospinal form will present a combination of both spastic and flaccid paralyses. It has not been my fortune to see any of this type.

The ataxic type will present nystagmus and disturbances of equilibrium, and is usually present along with manifestation of lower motor neuron injury.

The meningitic form is an extremely interesting type. The picture resembles so closely that of an acute purulent meningitis that one would almost invariably call it that until the spinal fluid gives one the hint that one is dealing with the meningitic form of poliomyelitis. The first case of the epidemic was one of this type. This form may also present evidence of cranial nerve paralysis, but the meningeal symptoms dominate the clinical picture.

The abortive form will prove, in our opinion, to be the most common of all the types mentioned above. Most students of the subject consider that there are at least as many of this type as of the sum total of the other forms. It manifests itself in a manner similar to that of the paralytic type, except that it presents no paralysis. The knee jerks may disappear and there may be a very transient paresis, but there is no actual paralysis. These are the cases that may be diagnosed as influenza or gastrointestinal disease, and it is this form which renders the proper quarantine control inadequate.

Diagnosis.—The diagnosis of poliomyelitis is both easy and difficult. It requires no great diagnostic ability to recognize the frankly paralytic forms, such as the cortical and the spinal forms, especially in the presence of an epidemic. The diagnoses of the ataxic and meningitic forms are confirmed by the examination of the cerebrospinal fluid.

The abortive form, especially where knee jerks are present, can be diagnosed with any degree of certainty only by lumbar puncture and examination of the fluid. The Meningitis Division of the New York Department of Health advises physicians who have patients that present vague meningeal symptoms without any adequate explanation of their causation to perform lumbar puncture and have the spinal fluid examined. It is through this agency that we shall be able to obtain a more adequate idea of the relative number of abortive cases, and also it is by the extension of this laboratory aid that we shall be able to more effectively prevent the spread of the disease.

The spinal fluid in poliomyelitis presents changes which deviate in practically all cases from the normal. While the changes are definite, they are in no sense specific. In other words, given a spinal fluid for examination without any further information added, one could not say that it is a poliomyelitis fluid. One must needs have an adequate clinical history in conjunction with knowledge of abnormal changes in the spinal fluid. The reason for this is apparent. There is no specific organism as yet that can be demonstrated in the spinal fluid of poliomyelitis. Other diseases, as tuberculous meningitis, lues of the central nervous system, typhus, and some cases of whooping cough in the convulsive stage, present changes in the spinal fluid in many instances strikingly similar to those of poliomyelitis. The finding of the tubercle bacillus will at once establish a diagnosis of tuberculous meningitis. But we find the bacillus in smear in only about 50 to 60 per cent. of known tuberculous fluids. That leaves about 40 to 50 per cent. of tuberculous fluids against which to strike a differential diagnosis. This would seem to present an insurmountable difficulty, but it is fortunate for the clinicians that the diseases which present changes in the spinal fluid so much like that of poliomyelitis are clinically easily distinguishable. Whooping cough and typhus have characteristics which separate them easily. Lues can be put aside by history and Wassermann reaction. That leaves tuberculous meningitis in 40 to 50 per cent. of cases. In the great majority of cases a differential between tuberculous meningitis and poliomyelitis presents no difficulty. In the former there is a slow, gradual subfebrile onset, cold in type, with meningeal symptoms developing after a week or two. In the latter there is most commonly an abrupt onset, with high fever, florid in type, with meningeal symptoms appearing very early in the disease. This method of diagnosis serves in the great majority of cases. There are cases of acute onset with high fever in tuberculous meningitis, but they are, fortunately,

rare. This type, too, is more apt to present the bacillus in smear. Then difficulty may arise when an accurate history is not obtainable. Some rare forms of epidemic meningitis may present a fluid not unlike some that we find in poliomyelitis.

The spinal fluid in poliomyelitis is, as a rule, clear by reflected light. By transmitted light can be seen a suspension of material in a good many instances. Occasionally the fluid is opalescent and even slightly turbid.

Chemical examination shows it to contain albumin, globulin, and a copper-reducing substance, probably dextrose. Albumin and globulin are abnormal constituents, and indicate inflammatory change. The presence of reducing substance is normal, and absence of the same is abnormal. The absence of the reducing substance is very uncommon, and when it is met with it is in the severest cases of the meningitic form. The diminution or absence of the reducing substance indicates that the pathological process has involved the choroid plexus, which is the mechanism that secretes this substance into the spinal canal. The quantity of these constituents is graded from 1+ up to 4+, depending upon the intensity of the reaction.

The cytology of poliomyelitis fluids is characterized in the great majority of instances by a great preponderance of small mononuclear cells with a fair sprinkling of large mononuclears, or perhaps they may be called endothelioid cells. This latter cell is not commonly found in the fluid of tuberculous meningitis, and therefore may give us a hint as to whether or not the fluid under examination is a poliomyelitis fluid. When this type of cell is found in sufficient numbers, we suspect the possibility of poliomyelitis. It is, however, by no means pathognomonic of this disease.

Another cell which the writer has noted with sufficient frequency to attract attention is a glia-like cell. This cell looks strikingly like the glia cells of the central nervous system, from which, in my opinion, they migrate into the cerebrospinal fluid. The writer has not up to the present time encountered a cell of this type in the fluid of tuberculous meningitis, and when found has considerable diagnostic weight, especially when the clinical history of the case is not very definite. It is a well-known fact that the glia cell of the central nervous system can assume phagocytic properties, and that, in my opinion, is how they find their way into the spinal fluid. The glia cell, as well as both the large and small mononuclear cells, may contain very small, deep-staining granules and rod-like bodies, the significance of which is at the present time unknown.

As to microorganisms in the spinal fluid, none have up to the present time been found. While the spinal fluid presents no specific characteristics *per se*, yet it presents, in the great majority of cases, definite changes, without the knowledge of which great numbers of abortive and atypical cases would go begging for a diagnosis. To summarize, the changes in the spinal fluid of poliomyelitis are as follows:

1. The fluid is increased and many times under pressure.

2. It is in nearly all cases clear to the naked eye, but occasionally it may be opalescent or even slightly turbid.

3. Albumin and globulin are increased as a rule to 1+, and not infrequently to 3+ and rarely to 4+.

4. Fehling's solution is in the great majority of cases promptly reduced.

5. The cells are definitely increased at some stage of the disease, usually in the early stage.

6. The predominating cell type is the small mononuclear up to 90 per cent. of the total. There are a number of fluids, particularly those which are opalescent or slightly turbid, in which there is a preponderance of the polynuclear cell up to as high as 75 per cent.

The fluid that offers the greatest difficulty of differentiation is that of tuberculous meningitis. Normal fluids, while impossible of differentiation macroscopically, show no abnormal constituents from either the chemical or the cytological aspect.

Lumbar puncture is a simple and safe procedure, and resort to it should be had whenever there is question of diagnosis of a condition which presents evidences of meningeal and brain or cord disease. Many an obscure condition may be rendered simple by the thorough examination of the spinal fluid.

Prognosis in poliomyelitis is at best a hazardous venture. Cases which the clinician considers very grave may clear up within 24 to 48 hours and present the most astonishing improvement. On the other hand, there are cases which, apparently mild, will rapidly develop fulminating symptoms and pass out in a few hours. In most of the rapidly fatal cases death occurs within the first six or seven days from the onset; usually it is three to four days. Therefore, if a case lives for one week, the chances of preservation of life are much improved. This is true particularly of the spinal form. The cortical and meningitic types, however, may go on to two or three weeks before passing out. There are some unusual cases of the disease which present symptoms of the abortive type. These clear up rapidly in a day or two and one will consider the danger past. Four or five days later the child will be seized with an acute onset, high fever, and paralysis which may prove to be of the Landry type. This form is sometimes called the relapsing form. There is another type of the mild case in which there are all the initial symptoms of a true case, a subsidence of these symptoms followed by an interval as great as two weeks before the typical flaccid paralysis appears, the paralysis in these cases not being ushered in by stormy symptoms. Of all the types classified above, the spinal form leads in the production of mortality. This is due without a doubt to the great preponderance in numbers of this type over the other. The meningitic and encephalitic forms are just as serious or more so perhaps than the spinal form. When the figures in this epidemic are collected there will be found a higher relative mortality in these types than in the spinal form.

As to the age, the mortality figures cited above indicate that the disease is particularly fatal to children under five years of age. This figure is perhaps misleading inasmuch as the great preponderance of cases occur among children under five years of age. The writer's observations in this epidemic lead him to believe that poliomyelitis in the adult is a very grave disease. The mortality percentage in cases above 16 years of age will exceed the mortality figures of the epidemic at large. It is interesting to note at this juncture that the adult only rarely presents the spinal form, the more common types at this age being the meningitic or encephalitic varieties.

The prognosis as to the residual paralysis is guess work. Some of the rapidly ascending types even with involvement of respiratory center have recovered without a sign of residual paralysis.

This, however, is not common; whereas, cases in which there is only one limb involved may present a permanent paralysis in that limb; 70 to 80 per cent. of cases presenting paralysis have residuals. It is the way of wisdom, especially in the present epidemic, with a mortality of 22 per cent., and the manifestation of marked eccentricities in the course of the disease, to be ultra-conservative. It will prevent many embarrassing situations and preserve brilliant reputations.

Prophylaxis.—The demonstration of the fact that poliomyelitis is transmitted from one human being to another furnishes a rational basis for the prosecution of prophylaxis. However adequate, prophylaxis in the matter of isolation of disease carriers is rendered most difficult by the existence of the very mild cases that go undiagnosed. Until this type of case is taken more seriously by the general profession and unremitting efforts are made to prove whether or not it is poliomyelitis, then and then only shall we approach a more perfect isolation of the virus.

The question of transmission of the disease by healthy adults or other immunes deserves much serious study. This method of transmission will be proved to have had a large share in the rapid dissemination of the disease. In view of these facts, personal contact of all kinds should be reduced to the possible minimum; such as the prevention of gatherings of children and adults, and even of adults. Osculation in time of an epidemic of poliomyelitis is the height of folly. Wherever possible, persons should occupy beds singly.

In view of the finding of the virus in dust, though this work has not been confirmed, it would be no great wrong to advise absolute cleanliness in the home. The possibility of transmission by food has not received serious consideration thus far. It would be well that foods, wherever possible, be boiled or subjected to heat before consumption. The slogan especially in time of epidemic should be a clean body, a clean home, and a clean city.

When diagnosed, all cases should receive strict isolation, preferably in a hospital. Suspicious cases should be strictly quarantined in their homes until diagnosis is confirmed or negatived by examination of spinal fluid.

As to the use of gargles and sprays in the nose and throat, one cannot place too much dependence on them. Contact is *the* method of transmission. Prevent that and there will be no need of gargles and sprays. If one puts too much credence in the efficiency of solutions in the nose and throat one is apt to be careless in the prevention of that most important element in transmission of disease—contact.

There is no method of specific prevention by such means as the Pasteur treatment or vaccination against smallpox. Experimental work on monkeys by Landsteiner and Levaditi,[8] Romer and Joseph,[9] Krause[10] in Germany, and by Flexner[11] and coworkers in this country is decidedly encouraging. Stimulation of search for a method of specific prevention is bound to result from the intense interest aroused in the subject by the present epidemic. When a satisfactory method is evolved, poliomyelitis will have been robbed of its terrors. Epidemics of poliomyelitis will be as rare as those of smallpox are to-day.

Treatment.—Treatment of the acute stage consists chiefly in isolation; absolute rest and good nursing night and day. Urotropin is advised in good sized doses, about five grains every four hours for a child of three to five years of age and graded up and down according to age. When using this drug, keep a sharp watch for bladder irritability. If it appears, diminish the dose or discontinue entirely, preferably the latter. This drug is recommended by Flexner on the basis of some experimental work, in which the incubation period of the disease in a monkey was retarded for a period of forty days through the use of this drug.

Lumbar puncture may prove of great help in the meningeal and cortical types, and in any case which presents marked meningeal symptoms.

Specific therapy by the use of serum derived from persons who have passed through an attack has been tried by the Scandinavian physicians and by Netter[12] of France, with inconclusive results. The rationale of the treatment is as follows: Serum from a recovered case exerts upon active poliomyelitis virus a neutralizing effect when the two are kept in contact for a period of 24 hours, so that when this neutralized virus is inoculated into the brain of a monkey, it no longer produces the symptoms of poliomyelitis; whereas, the control monkey inoculated in a similar manner but with virus not previously acted upon by the immune serum comes down in the usual time and manner. This experiment demonstrates conclusively the presence of antibodies in the blood of persons who have recovered from poliomyelitis. These antibodies have been demonstrated in the blood of persons as long as 30 years after the attack. Flexner[13] has shown in a rather small number of experiments on monkeys that when serum from such persons is administered intraspinally within 24 hours after the active virus is introduced into the brain and when the administration of the serum is continued for several days after the infective virus has been so introduced, such animals fail to come down with poliomyelitis. Experiments in treatment of actual monkey poliomyelitis by immune serum has to the writer's knowledge not yet been recorded. These facts, then, offer the basis for treatment with immune serum.

As to the possibilities of harm from the intraspinal administration of this serum, the practice is too recent and too limited to afford adequate observations on that point. From personal experience in a very few cases and from theoretical considerations, I fear that in some cases it is not without harm.

The introduction of a therapeutic serum into the subdural space of a case in which there is no evidence of meningeal inflammation as determined by the examination of the spinal fluid is followed in many instances by a marked meningeal reaction. Subsequent fluids withdrawn after the introduction of serum reveal evidences of meningeal inflammation. The fluid is usually turbid, due to great increase of cells; there is a 3 + to + 4 albumin and globulin, and there may be a diminution of the reducing substance. In other words, there are all the evidences of a purulent meningitis without the presence of microorganisms, an aseptic meningitis.

An aseptic meningitis in some cases is likewise set up in poliomyelitis upon the introduction of immune serum into the spinal canal. The writer feels that the superimposing of this condition upon an already existing edema and congestion of such a delicate and vital structure as the gray matter of the spinal cord may have, in some cases, a power for harm. Personally, I feel that it ought not to be

used in the spinal form for fear of stimulating the attack by the virus of the vital center of respiration. It is too delicate a mechanism to tamper with. Perhaps in the meningitic variety with no involvement of the cord it may prove of value. A study of this method of treatment is now under way at the Willard-Parker Hospital under supervision of the New York Department of Health Laboratories. When the figures are collated and assorted perhaps then we shall gain a true idea of the value of this method of therapy.

DREAMS AND DREAMERS.

By ISRAEL BRAM, M.D.,

PHILADELPHIA, PA.

INSTRUCTOR IN THE MEDICO-CHIRURGICAL COLLEGE.

"And Dreams in their development have breath,
And tears and tortures, and the touch of joy;
They have a weight upon our waking thoughts,
They take a weight from off our waking toils,
They do divide our being."

—Byron.

Dreams! What a wonderful, lace-like network of varied images the mere word suggests. What mysterious vistas of boundless mansions with sky-high ceilings and bottomless staircases—what terrible experiences o'er fearful precipices and blood-curdling encounters with ferocious beasts—what fabulous fortunes gained and spent—what grotesque combinations of numerous, widely varied images into wonderful, mysterious phantasies are exhibited to us by the evanescent pictures called dreams. How often does it seem a pity that these gloriously beautiful soap bubbles are doomed to vanish to eternity on awaking! Almost as mysterious a question as that of the hereafter, the subject of dreams confronts us as a silent sphynx; and though it has attracted the attention of man from the dawn of history, the sifting of the vast amount of material written on the subject reveals nothing but a few vague ideas of but relative rather than absolute practical value. The study of some of the phases and plausible theories of this peculiar state of mankind constitutes one of the most fascinating forms of mental recreation.

The literature of man is rich in dream fancies, and because of its very intangibleness and vagueness the dream has inspired facts to sweet songs, and has often even furnished the plot of a successful drama. Shakespeare found that "We are such stuff as dreams are made of, and our little life is rounded with a sleep." Novalis, the German poet, has written so beautifully of dreams that we cannot help quoting: "The dream is a barrier against the regularity and commonness of life—a free recreation of fettered fantasy, in which the pictures of life are united together, interrupting the seriousness of grown-up men with joyous children's play. Without the dream we should surely age earlier, and thus the dreams may be considered, perhaps, not a gift directly from above, but a delightful task—a friendly companion through life's toils."

It is said that Alexander's army would have been annihilated were it not for a dream in which Dionysius directed the means of safety.

In the Bible, dreams are considered the chosen method of the supernatural power to manifest itself. It was in a dream that Abraham was made the founder of nations by the Lord, who appointed him to teach the pagan world the errors of polytheism.

When Jacob was on his way to seek a wife among the daughters of Laban, he dreamt that he beheld a ladder extending from earth to Heaven, on which the Angels of God were ascending and descending, and he was promised that his seed should be as the dust of the earth. Subsequently the Angel of God spoke unto Jacob in a dream, saying: "Lift up now thine eyes, and see that all the rams which leap upon the cattle are speckled, ring-streaked, and grizzled; for I have seen all that Laban doeth unto thee. Now arise, get thee out from this land, and return unto the land of thy kindred." Thereupon Jacob, with Rachel, his wife, and Leah, stole away with their children, their cattle, and their goods, unawares to Laban, the Syrian. The third day after Jacob's flight Laban first heard of it, and after a seven days' journey overtook him in the Mount Gilead. Meantime, God came to Laban, the Syrian, in a dream by night, and said unto him: "Take heed that thou speak not to Jacob either good or bad." When Laban met Jacob he chided him for going away secretly and said: "It is in the power of my hand to do you hurt, but the God of your father spake unto me yesternight, saying, 'Take thou heed that thou speak not to Jacob, either good or bad.' "

It was the recital of one of his dreams that instigated Joseph's brethren to sell him into Egypt. Having correctly interpreted the dreams of the King's chief butler and chief baker (who were his fellow-prisoners) his fame spread through the land, so that when the King himself had a perplexing dream, Joseph was sent for; and so impressed was the king by his ability that Joseph became very powerful, and virtually ruler over all the land of Egypt, and was thus enabled subsequently to save his brethren and prepare the way for the escape of the Children of Israel from bondage to a land flowing with milk and honey.

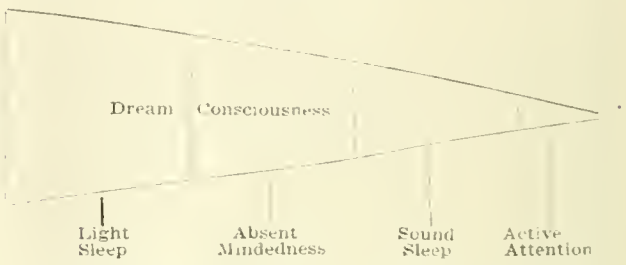
While Daniel and his three comrades were living at the court of Nebuchadnezzar—"God gave them knowledge and skill in all learning and wisdom," and Daniel became proficient in the interpretation of all visions and dreams. "When two years later Nebuchadnezzar had a dream which he had forgotten, he issued a decree for the slaughter of all his wise men and magicians, because they could not make known to him the dream and its interpretation." Daniel saved their lives and his own by revealing to the king "the visions of his head upon

his bed," and their interpretation. One of the memorable results of this dream was that Nebuchadnezzar at last confessed to Daniel that his God was the God of gods and the Lord of kings, and he made Daniel himself to rule over the whole province of Babylon and to be chief governor over all the wise men thereof. Nebuchadnezzar in due time had another dream, which Daniel was called upon to interpret. It was of painful import. The king was to be driven from men; his dwelling was to be with the beasts of the field, he was to be made to eat grass as oxen, and to be wet with the dew of Heaven, and seven times were to pass over him until he should know "the Most High ruleth in the kingdom of men and giveth it to whomsoever he will." "At the end of these days," said Nebuchadnezzar in his official proclamation of this experience, "I lifted up mine eyes unto heaven, and at the same time mine understanding returned unto me; and for the glory of my kingdom excellent greatness was added unto me."

The definition of the term "dream," as of other mysterious natural states and forces, is practically impossible. We are able usually to distinguish between the shock produced by electricity and the heat experienced when a boiling kettle is touched, but neither the term "dream" nor "electricity" is capable of a concrete, lucid definition.

We are possessed of two mind mechanisms, consisting of a consciousness which predominates our thoughts and actions when awake, and a "dream consciousness" or "subconsciousness" which rules, because of sleep or some other reasons, when the usual or "day" consciousness is dormant. The dream consciousness is usually present also in the waking state, the degree depending chiefly on the mental or psychological make-up of the individual. We all do a certain amount of dreaming during the performance of our daily duties. In the midst of any mental or physical application, the trained observer will easily catch himself in moments of dream consciousness, to find that he made brief mental excursions to some distant lands. On the perusal of this article, the reader may at the same time recall that he dreams often or rarely; and perhaps, from time to time images of people met or thoughts of duties performed or to be performed will flit through his mind. The vividness of these day-dream images and their individual duration will, of course, be in inverse proportion to the degree of the concentration of attention to the article before the reader. This other self, acting independently, may conjure up thought upon thought, despite the fact that the reader is interested in this paper and assimilating its essential points. These subconscious impressions of the waking hours closely resemble dreams; indeed, it is impossible to strictly separate them from the dreams of the night, excepting that in the latter the images are often exaggerated, often confused into a chaotic jumble, frequently presenting conditions physically impossible; while in the former, though fleeting, the images do not crowd, are more orderly, and actions are physically possible. There is in our conscious life a luxuriant halo of these subconscious associations; but the normal person's mind is developed and trained to keep them where they belong—in the background, a condition consistent with sanity and mental efficiency. The ability to suppress these subconscious impressions constitutes the essence of mental attention and concentration. The more absent-minded we are the more vivid, coherent and prolonged these subconscious associations become, the next step being light sleep, then sound sleep. The chronically absent-minded person, therefore, rightly deserves to be considered in a degree asleep and a dreamer.

Active attention and sound sleep hold the substratum of mental activity or dream consciousness in obeyance; the most favorable conditions for dreaming being light sleep and absent-mindedness. The gradations of frequency and vividness of dreams, in ratio to the degree of waking consciousness, may be thus diagramatically illustrated:



However sound a sleep may be, dreams probably occur, though one may not be able to recall them on awaking. The mind is never entirely asleep; all experimental evidences seem to confirm this opinion. The more imperfect the sleep, however, the greater the vividness of dreams and the more likely of recall to memory in awaking. The occurrence of sensory stimulation determines the reduction in the soundness of sleep and is in direct ratio with the occurence of "recallable" dreams, varying from the dream image of an orchestra concert in the presence of the buzzing sound of a mosquito close to the sleeper, to the nightmare of being stabbed by a band of ruffians, as a consequence of the gastric insult from the indigestion of a modern banquet the night before, in which perhaps several forms of meat, fish, and lobster were prominent constituents.

Freud, the eminent psychologist, remarks, "Every distinctly perceived noise or other sense impression gives rise to a corresponding dream picture. The rolling of thunder takes us into the thick of a battle; the crowing of a cock may be transformed into human shrieks of terror; the creaking of a door may conjure up dreams of burglars breaking into the house. When one of our blankets slips off at night, we may dream that we are walking about naked or that we are falling into water. If we lie diagonally across the bed with the feet extending beyond the edge, we may dream of standing on the edge of a terrifying precipice or falling from a great height. Should our head accidentally get under the pillow, we may imagine a big rock hanging over us and about to crush us under its weight."

There are certain provisions of nature which may be justly regarded as auxiliaries to sleep and universal in their operation, and which seem to have for their purpose the removal of sources of stimuli. At uniform intervals in every twenty-four hours of our life the sun withdraws its light and covers us with a mantle of darkness. This not only invites sleep by withholding a stimulus which discourages it, but practically interrupts or modifies all forms of industrial activity; it interferes seriously with locomotion; it suspends most of the plans and occupations which engage our attention during the sunlit hours of every day, and emancipates us for a few hours from the dominion of our natural propensities and passions, which engross so much of our time and thought by day. Nor is it only by the setting of the sun that we are invited daily to give

pause for a few hours to our worldly strifes. In sleep all the sensorial and other functions dependent upon or under the government of the will are relaxed. To secure this relaxation we seek positions, places and all other conditions best calculated to shelter us from light, noise and all other awakening influences. Like man, the lower animals at such times choose a retired place, assume postures which demand no voluntary effort and which expose them least to external forces which may chance to disturb them. The serpent coils itself up so as to expose as little of its superficial surface as possible to disturbance; the bird conceals his head under his wing; the porcupine covers his eyes with his tail; the skunk rolls himself into a ball; the dog covers his face with his paw. Why should the ploughman leave his plough in its furrow when the sun ceases to light its way? Can any other satisfactory reason be suggested than that he may for a few hours be as one dead to the concerns of his farm and plough, and his soul for a time be freed from their distractions? Whatever else may be the final purpose of sleep, that purpose also obviously must be among the contributory purposes of nocturnal darkness, for that is one of its inevitable and periodical consequences. The subconscious element of our waking state consists of memories which appear and disappear, occupying our mind in turn. But they differ from memories of our dream state in that they are always memories which are closely connected with our present situation, our present action. I recall at this moment the remarks of Herbert Spencer on sleep, because I am discussing the subject of dreams; and this act orients in a certain particular direction the activity of my memory. The memories that we meet while waking, however distant they may at first appear to be from the present action, are always connected with it in some way.

Our memories, at any given moment, form a solid whole, a pyramid, so to speak, whose point is inserted precisely into our present action. But behind the memories which are concerned in our occupations and are revealed by means of it, there are others, thousands of others, stored below the scene illuminated by consciousness. Indeed, it is even said that all our past life is there, preserved even to the most infinitestimal details, and that we forget nothing, and that all that we have felt, perceived, thought, willed, from the first awakening of our consciousness, survives indestructibly. But the memories which are preserved in these obscure depths, are there in the state of invisible phantoms. They aspire, perhaps, to the light, but they do not even try to rise to it; they know that it is impossible and that I, as a living and acting being have something else to do than to occupy myself with them. But suppose that, at a given moment, I became disinterested in the present situation, in the present action—in short, in all which previously has fixed and guided my memory; suppose, in other words, that I am asleep. Then these memories, perceiving that I have taken away the obstacle, have raised the trap door which has kept them beneath the floor of consciousness, and arise from the depths. They rise, they move, they perform in the night of unconsciousness. They rush together to the door which has been left ajar. They all want to get through. But they cannot, there are too many of them. From the multitudes which are called, which will be chosen? Thus arises the apparent *inconsistency* of dream images.

During a brief period of a few minutes dream pictures corresponding to hours of time may be enacted. Thus, a dreamer fell asleep while listening to some one who was reading to him and awoke again toward the termination of a sentence that had been begun when he dozed off. The actual duration of sleep was about ten seconds or less, yet he dreamt of a storm, shipwreck, and heroic rescue which would occupy at least three hours of time in real life. There is no conception of time or space in dreams; we live in an ideal world. These peculiar characteristics of dreams are due to the fact that volition and attention are absent; the mind has no control over the objects that crowd upon it. There is no concentration or fixity of thought necessary for memory. In other words, in the dream state there is a *decentralization* of the mind. Ideas, grotesque, often confused, arise spontaneously, crowd upon the mind, become vivid and vanish. Dreams usually leave only a faint impression on the memory, so that on waking, what was at first vivid and distinct, fades rapidly and insensibly away.

There is a peculiar tendency to exaggeration during dreams. A homely person or object becomes ugly, a beautiful being becomes the most handsome in the universe. A tall person is a giant, a short individual a midget. If we trip and fall down a flight of stairs, the flight is never ending, and we never reach the bottom, but continue on our journey until we awake. An important event relating to ourselves or those near to us may never be dreamed about, but a wart or mole on the forehead of a stranger may be dreamed of repeatedly.

In a dream we become no doubt *indifferent* to logic, but not *incapable* of logic. There are dreams when we reason with correctness and even with subtlety. I might almost say at the risk of seeming paradoxical, that the mistake of the dreamer is often in reasoning too much. He would avoid the absurdity if he would remain a simple spectator of the procession of images which compose his dream. But when he strangely desires to explain it, his explanation, intended to bind together incoherent images, can be nothing more than a bizarre reasoning which merges upon absurdity. The dream is the state into which you naturally fall when you no longer have the power to concentrate yourself upon a single point, when you have ceased to will.

In the dream the same faculties are exercised as during waking, but they are in a state of tension in the one case, and of relaxation in the other. The dream consists of the entire mental life minus the tension, the effort, and the bodily movement.

From this essential difference can be drawn a great many others. We can come to understand the chief characteristics of the dream. But I can only outline the scheme of this study. It depends especially upon three points: the incoherence of dreams, the abolition of the sense of duration that often appears to be manifested in dreams, and finally, the order in which the memories present themselves to the dreamer, contending for the sensations present where they are to be embodied.

The incoherence of the dream seems easy enough to explain. As it is the characteristic of the dream not to demand a complete adjustment between the memory image and the sensation, but, on the contrary, to allow some play between them, very different memories can suit the same sensation. For example there may be in the field of vision a green spot with white points. This might be a lawn spangled with white flowers. It might be a billiard table with its balls. It might be a host of other

things besides. These different memory images, all capable of utilizing the same sensation chase after it. Sometimes they attain it, one after the other. And so the lawn becomes the billiard-table, and we watch these extraordinary transformations. Often it is at the same time, and altogether, that these memory images join the sensation, and then the lawn will be a billiard-table. From this comes those absurd dreams where an object remains as it is and at the same time becomes something else. As I have just said, the mind, confronted by these absurd visions, seeks an explanation and often thereby aggravates the incoherence.

As for the abolition of the sense of time in many dreams, that is another effect of the same cause. In a few seconds a dream can present to us a series of events which will occupy, in the waking state, entire days. When we are awake we live a life in common with our fellows. Our attention to this external and social life is the great regulator of the succession of our internal states. It is like the balance wheel of a watch, which moderates and cuts into regular sections the undivided, almost instantaneous tension of the spring. It is this balance wheel which is lacking in the dream. Acceleration is no more than abundance a sign of force in the domain of the mind. It is, I repeat, the precision of adjustment that requires effort, and that is exactly what the dreamer lacks. He is no longer capable of that attention to life which is necessary in order that the inner may be regulated by the outer, and that the internal duration fit exactly into the general duration of things.

It remains now to explain how the peculiar relaxation of the mind in the dream accounts for the preference given by the dreamer to one memory image rather than others, equally capable of being inserted into the actual sensations. There is a current prejudice to the effect that we dream mostly about the events which have especially preoccupied us during the day. This is sometimes true. But when the psychological life of the waking state thus prolongs itself into sleep it is because we hardly sleep. A sleep filled with dreams of this kind would be a sleep from which we came out quite fatigued. In normal sleep our dreams usually concern themselves rather with the thoughts which we have passed through rapidly, or upon objects which we have perceived almost without paying attention to them. If we dream about events of the same day, it is the most insignificant facts, and not the most important which have the best chance of reappearing.

In accepting the definition that a dream is a condition of physiological delirium we approach a very plausible explanation of dreams. An eminent observer has said: "Find out all about dreams, and you find out all about insanity." While this may appear a trifle exaggerated, yet most alienists agree that dreams and many forms of mental aberration have a great deal in common. Is it not possible, let us ask, for the substratum of mental activities known as dream consciousness, which lacks so much in logic and reasoning, and is totally devoid of will, to gain the ascendency under certain adverse conditions, thus to constitute a form of mental aberration classified under insanity? From the summing up of such evidence as he collected, Ellis concludes: "If we pierce beneath the surface we seem to reach a psychic stage in which the dreamer, the madman, the child, and the savage alike have their starting point. It thus happens that the way of thinking and feeling of the child, the savage and the lunatic each furnish a road by which we may reach a psychic which is essentially that of the dreamer."

Charles Lamb tells us that during the early part of his life he was constrained to retire to a lunatic asylum, where he was detained for several months. In a letter to his friend, Coleridge, written a few years after his recovery, he said: "At some future time I will amuse you with an account, as full as my memory will permit, of the strange turn my frenzy took. I look back upon it at times with a gloomy kind of envy; for while it lasted I had many, many hours of pure happiness. Dream not, Coleridge, of having tasted all the grandeur and wildness of fancy till you have gone mad."

The so-called "nightmare," the terrifying dream, is usually the result of an unpleasant sensory stimulus, often of pathological origin. Dr. Franklin, in a letter once written to a Miss on the act of encouraging pleasant dreams, said: "In general, man, since the improvement of cooking, eats about twice as much as Nature requires. Suppers are not bad if we have not dined, but restless nights naturally follow hearty suppers after full dinners. Indeed, as there is a difference in constitutions, some rest well after these meals; it costs them only a frightful dream, and an apoplexy, after which they sleep till doomsday."

In some dreamers the activity of the cerebrum is such that the train of thought leads to movement, and the sleeper may be heard muttering, tossing about, or making gestures. The extreme cerebral activity in sleep is seen in somnambulism, which is arbitrarily divided into four types: (1) Those who speak without acting (a common variety, often observed in children, and not usually considered somnambulistic); (2) Those who act without speaking (the most common variety); (3) Those who act and speak; (4) Those who not only act and speak but who also have an active sense of touch, sight, and hearing. This fourth class is most rare, and merges into the condition of mesmerism or hypnotism.

Sometimes the actions performed by a subject of somnambulism are of complicated character, and bear some relation to the daily life of the sleeper. Thus a cook has been known to rise out of bed, carry a pitcher to a well in the garden, fill it, go back to the house, fill various vessels carefully without spilling a drop, then return to bed and have no recollection on awaking of what had transpired. Again, somnambulists have been known to write letters and reports, execute drawings, and play upon musical instruments. Frequently they have gone along dangerous paths, executing delicate movements with precision; indeed, the somnambulist seems to have perceptions supernaturally acute, walking with confidence and safety along roofs of houses, on the banks of rivers, and other perilous places where nothing could have tempted him to go when awake. The following is another interesting example of somnambulism: "A girl of twenty-four, a hospital patient, went to the staircase leading to the nurses' quarters, suddenly turned around, and went to the wash house. The door being closed, she groped for a time and went toward the women's dormitory, in which she formerly slept. She went up to the top of the house where this dormitory was, opened a window leading to the roof, went out of the window, walked along the gutter (under the horrified eyes of the nurse who followed her, and who did not dare speak to her), went in again by another window, and proceeded downstairs."

The beloved French literary genius, Voltaire, in

his "Philosophical Dictionary," thus presents his views and experiences on dreams and dreamers: "I have known advocates who have pleaded in dreams, mathematicians who have solved problems, and poets who have composed verses. I have made some myself, which are very passable. . . . It is, therefore, incontestable that consecutive ideas occur in dreams, as well as when we are awake, which ideas as certainly occur in spite of us. We think while sleeping, as we move in our beds, without our will having anything to do either in the motive or in the thought. . . . A man profoundly afflicted at the death of his wife or his son sees them in his sleep; he speaks to them, they reply to him, and to him they have certainly appeared. It is, therefore, impossible to deny that the dead may return; but it is certain, at the same time, that these deceased, whether inhumed, reduced to ashes, or buried in the abyss of the sea, have not been able to reserve their bodies; it is, therefore, the soul which we have seen. This soul must therefore be extended, light, and impalpable, because in speaking to it we have not been able to embrace it.

"Dreams also appear to me to have been the sensible origin of primitive prophecy or prediction. What more natural or common than to dream that a person dear to us is in danger of dying, or that we see him expiring? What more natural than that such a person may really die soon after this ominous dream? Dreams which have come to pass are always predictions which no one can doubt, no account being taken of dreams which are never fulfilled; a single dream accomplished has more effect than a hundred which fail. Antiquity abounds with such examples. How constructed are we for the reception of error! Day and night unite to deceive us! . . .

"But how, all the senses being defunct in sleep, does there remain an internal one which retains consciousness? How is it, that while the eyes see not, the ears hear not, we, notwithstanding, understand in our dreams? The hound renews his chase in a dream; he barks, follows his prey, and is present at the death. The poet composes verse in his sleep; the mathematician examines his diagram, and the metaphysician reasons well or ill; all of which there are striking examples.

"In one of my dreams I supped with Mr. Tourón, who appeared to compose verses and music, which he sang to us. I addressed these four lines to him in my dream:

Thy gentle accents, Touron dear,
Sound most delightful to my ear!
With how much ease the verses roll,
Which flow, while singing, from thy soul!

"In another dream, I recited the first canto of the 'Henriade' quite different from what it is. Yesterday I dreamed that verses were recited at supper, and that some one pretended they were too witty. I replied that verses were entertainments given to the soul, and that ornaments are necessary in entertainments. I have, therefore, said things in my sleep which I should have some difficulty to say when awake; I have had thoughts and reflections, in spite of myself and without the least voluntary operation on my own part, and nevertheless combined my ideas with sagacity, and even with genius. We should never be good philosophers except when dreaming!"

Dreams are not always a confused chaos of events. There are instances in which dreams were characterized not only by the most sane concentration and continuity of thought, but also in which the images were of considerable use to the dreams. Often what appears to be beyond human ability is accomplished through dream ideas and inspirations. There are on record numerous instances of writers who for want of further ideas became discouraged and put aside a work to which they had been devoting a vast amount of energy and time. Suddenly they would awake some morning to find themselves possessed of the key to the successful issue of their toil. The same has been observed of many prominent inventors.

Paganini, the great violinist, once dreamt that the devil was pacing up and down his room playing his violin. The music played by his diabolic majesty was so weirdly mysterious, entrancing, and wonderful, that he was awakened with a start. He looked about, rubbed his eyes, and realizing that it was but a dream, rushed to his work desk to jot down the composition as he remembered it. The result is the wonderful composition known as "The Devil's Trill," recognized to-day as one of the most difficult, beautiful, and wonderful works ever composed for the violin, and is a constituent of the repertoire of every violin virtuoso.

It seems that in the "useful" dreams, occurring at times in inventors, writers, composers, and others, there is the possession in the subconscious mind of the knowledge yearned for, but because of the extreme anxiety of the individual, and also the rush of daily ideas and thoughts upon the mind during the waking hours, the subconscious ideas are crowded out. During sleep those ideas or images are released, coming forward with a sudden bound, like caged birds suddenly freed. The suddenness of this release of the novel idea or image may be great enough to awaken the dreamer with a start.

In conclusion, we cannot help feeling, as intelligent mortals, that dreams are a godsend, and that pleasant dreams should be encouraged. The way to court pleasant dreams is to avoid the causal factors of unpleasant ones. The proper care of the digestive and other functions, the avoidance of emotional excitement, and the maintenance of a cheerful, kindly spirit toward all the world are conducive to the avoidance of nightmares, and the occurrence of sound, healthful, rejuvenating sleep; and if dreams occur they are as a gift of Heaven, or a taste of Paradise. The blissful dream of the man or woman of good habits and clear conscience carries body and soul in a fairy bark away from this vale of toil and tears to lands of joy, of nectar and ambrosia, to return at purple daybreak.

"Sweet sleep be with us, one and all!
And if upon its stillness fall
The visions of a busy brain,
We'll have our pleasure o'er again,
To warm the heart, to charm the sight,
Gay dreams to all! Good-night, Good-night."

Pancreatic Function in Alcoholic Venous Cirrhosis of the Liver.—Udaondo and two others have studied five cases of hepatic cirrhosis with autopsy control. In every case the pancreas was the seat of lesions corresponding to the type of interstitial sclerosis. These undoubtedly aggravated the course of the hepatic disease and hastened death. Pancreatic perturbation was shown clinically by the characteristic diarrhea, precocious cachexia, and sensory syndrome. An exact diagnosis was made by clinical methods in each case. All essential details were present including results of histological examination. Little or no improvement was obtained from treatment. The cachexia was progressive and soon ended fatally.—*Revista de la Asociación Médica Argentina.*

TUBERCULOSIS AND CANCER.

A POSSIBLE EXPLANATION OF THE LONG-DISCUSSED QUESTION OF THEIR MUTUAL ANTAGONISM WITH THE SUGGESTION OF THE USE OF TUBERCULIN FOR THE PREVENTION OF RECURRENCE OF CANCER.

By WILLIAM M. DABNEY, M.D.,

BALTIMORE, MD.

THE question of antagonism between diseases has long occupied the attention of physicians and that apparent clinically between cancer and tuberculosis has, as is well known, been the subject of a great deal of discussion in the past. The literature on the subject is voluminous, but as the object of this article is to bring to notice certain particular features only it has seemed unnecessary to go into a prolonged discussion of the reasons which finally led the majority of medical men to conclude that this supposed antagonism was apparent rather than real. Suffice it to say that exhaustive and critical autopsy findings finally brought this about, and in fact led some authors to assert that not only was there no antagonism between these diseases, but that tuberculosis in some cases played a definite causative role in the subsequent development of cancer, this being especially true of so-called skin cancer.

That this supposed antagonism is apparent rather than real is probably true as regards tuberculosis in general, but to the writer it has appeared questionable as regards active tuberculosis, and one of the objects of this article is to present the reasons which have led him to adopt this attitude at variance with the trend of opinion of to-day.

When one considers the widespread dissemination of tuberculosis, so widespread, in fact, that it has been stated that practically no individual who has reached the age of 40 years has escaped it, it is evident that autopsy records leading to a verification of the question of the antagonism between these two diseases could reach but one conclusion, especially when one considers the additional fact that cancer may be said to be rare under 40.

Modern physicians and surgeons, being well aware that pathology is to medicine the court of last resort, have naturally accepted their exhaustive and accurate autopsy findings as conclusive and as deciding in the negative the question of antagonism between these two diseases. As showing, however, how firmly rooted the idea has become it is only necessary to state that since the question has been generally accepted as settled, some exponent of the positive side has occasionally arisen, only to be downed by the weight of evidence as presented by an exponent of the negative. Among those in comparatively recent years holding the positive view is G. W. McCaskey, who in an article published in the *American Journal of the Medical Sciences*, July, 1902, stated that he found cancer present in 1.4 per cent. of cases of active tuberculosis, and noted in addition that there had been a retrogression of the cancer after the injection of tuberculin, the use of which he suggested in his article. In spite of all this, however, almost any physician or surgeon of large experience, if asked whether he has ever seen active tuberculosis and cancer combined, will reply either in the negative or that he has seen such a combination very infrequently.

Such being the case, the question arises how can these divergent opinions be reconciled? The writer believes this possible and suggests the following explanation: Pathologists in making complete and careful autopsies would naturally find evidences of tuberculosis which to the physician would be unknown. These tuberculous lesions, although properly classified as such in autopsy reports, are clinically unrecognizable, and as a consequence it is only the active tuberculous lesion which is likely to come to the notice of the examining physician or surgeon. Their conclusions, therefore, as to the supposed antagonism between these two diseases would be largely confined to such cases as presented both diseases in a more or less active state at the same time, whereas the pathologist at the autopsy table must draw his conclusions from the actual anatomic findings. To the writer, consequently, it would seem that an actual antagonism exists between active tuberculosis and cancer, and he offers the following in support of his belief:

Tuberculosis has a tendency to produce a lymphocytosis, and as Murphy and Morton of the Rockefeller Institute have shown in an article published in the *Journal of Experimental Medicine* for August, 1915, lymphoid activity is an essential factor in the immunity process of artificially engrafted cancer, it would seem that those cases of tuberculosis which brought about a condition of lymphoid activity would exert an inhibitory influence on cancer.

Accepting these deductions as facts, the question arises, of what use can they be made clinically? It would seem to the writer that tuberculin which, according to some authors, certainly stimulates lymphoid activity, would meet the requirements. Theoretically, a preparation derived from a case or group of cases of proven lymphoid activity would seem preferable.

Furthermore, although lymphoid activity, as Murphy and Morton have shown, may be a necessary factor in the process of cancer immunity, it is by no means certain that it is the only one, or even the most essential one, and it is possible that tuberculosis may exert other and unknown inhibiting influences on cancer. Should this be true a proper preparation of tuberculin might in all likelihood have the same effect.

There are other and weighty advantages in the use of tuberculin for this disease, should it prove of use at all, and these are (1) its harmlessness properly given, and (2) that it would be applicable to practically all cases of cancer in view of the usual incidence of this disease after the age of 40 and the fact, as before stated, that almost every individual who has reached this age has had tuberculosis, and consequently, in some degree, would be sensitive to the action of tuberculin.

Following out the foregoing trains of thought, the writer has put them to the practical test. He has personally administered tuberculin to two patients suffering from cancer, and through the kindness of his friend, Dr. Hugh H. Young, head of the Department of Urology at the Johns Hopkins Hospital, it has been administered under the supervision of Dr. Norman B. Keith to three patients at the James Buchanan Brady clinic. A sixth case was at the writer's suggestion similarly treated by his friend, Dr. William A. Fisher, at the Union Protestant Infirmary, and a seventh by Dr. Charles W. Larned of this city.

The method of practical procedure varied somewhat as to type of tuberculin, dosage, frequency of administration. Careful differential counts of the

blood, however, both before and after administration of the vaccine, were made in all cases except in the last case, and these counts served as a practical guide.

A few remarks about this case, in which it was impossible to get differential blood counts, would seem proper. Miss X. Inoperable cancer of the esophagus. According to Dr. Larned the improvement in this patient's general condition was so noticeable following the use of tuberculin that members of the family remarked on it and asked what was being used to bring about this change. Her condition after three months or more of tuberculin therapy still continues improved. The treatment is being continued.

The work is as yet in a most unfinished state and naturally few, if any, correct conclusions can be drawn from so few cases, particularly in view of the fact that these cases were all inoperable and presented conditions anything but ideal for putting the foregoing ideas to the practical test. It is interesting, however, to note that of the six cases in which careful blood tests were made, four showed a change in the lymphocyte count following the administration of tuberculin, and from a clinical standpoint two, at least, of the seven showed an entirely unexpected improvement.

This being only a preliminary report, naturally but few cases have so far been tested. It would appear, however, that the results in these few cases would justify the statement that, given the proper preparation, dosage, etc., tuberculin will bring about a lymphocytosis in practically all cases.

There are several additional questions in connection with this subject which it would seem proper to present now. First: The statement has been made that cancer is occurring now at an earlier age than formerly, and that this is true even though one takes into consideration the greater diagnostic skill of the present-day medical man. Granted the truth of this, to what is it due? Is it due to the widespread crusade against tuberculosis and the consequent diminution in the comparative number of cases of what was formerly called consumption? Has the partial elimination of this phase of the tuberculous infection taken away to some extent one of nature's bulwarks, the lymphocyte, and rendered the individual more liable to cancer at an earlier age?

Furthermore, if it be true that cancer does develop now at an earlier age than formerly, would not this fact negative the following criticism which might be leveled against the foregoing ideas, namely, that active tuberculosis and cancer are rarely combined for the reason that the sufferer from active tuberculosis usually dies before reaching the so-called cancer age.

Second: Of what use, if any, would tuberculin be in those inoperable cases treated by radium and allied substances? So far as the writes knows, actual proof of the effect of radium on the blood is not available, but in two at least of the cases which have been cited the lymphocyte count was low. In one of these cases there was a dictinct drop in the lymphocyte count immediately following the first radium treatment, and on this account the low lymphocyte count in the other case was considered to have been the result of several radium treatments given some time previously.

Naturally, no positive conclusions can be drawn from two cases, but these facts, taken in conjunction with the statement made by Murphy and Morton that the *x*-ray exerts a markedly deleterious influence on lymphoid activity, would seem to indicate that the same was probably true of radium. Such being the case, the use of tuberculin to stimulate lymphoid activity during the course of radium treatment would seem indicated.

Third: Granted the use of tuberculin to be indicated in cancer, what form of tuberculin shall be used? Human or bovine? From the fact that bovine tuberculosis usually affects the glands and cancer is primarily disseminated by the lymphatics, would not the bovine appear to be the preparation of choice?

Would it not be possible to solve this question for each individual case by the use of the von Pirquet skin test, with vaccines obtained from both human and bovine bacilli? The preliminary dose to be given each case might also be estimated by the adoption of this method if one used two or more dilutions of each preparation and noted the resulting reactions.

It has been stated that von Pirquet's skin reaction produces a local lymphocytosis, which fact could likewise be made use of in the adoption of this method as a preliminary step in tuberculin therapy, especially in the case of superficial cancer.

It should not be understood that in presenting this article the writer makes any claim for it other than that above stated, namely, that, granted the necessity for lymphoid activity in the production of cancer immunity, any harmless substance which will bring this about would seem theoretically to be of use, and furthermore, it would appear that until the cause of cancer is discovered, any harmless procedure which has a certain amount of backing as the result of both clinical and experimental experience might have its possibilities for good if used in conjunction with surgery and in the inoperable cases with radium and allied substances.

The stimulation of further interest in the principles underlying the supposed antagonism between these two diseases, as well as others, would seem a result well worth the effort, even though the method advocated in the foregoing should prove of no value.

ANAPHYLAXIS TO MERCURY—WITH REPORT OF A CASE.

By M. ZIGLER, M.D.,

NEW YORK.

INSTRUCTOR, GENITOURINARY AND VENEREAL DISEASES, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, CHIEF OF CLINIC GENITOURINARY DEPARTMENT, LEBANON HOSPITAL.

During ten years' experience in the treatment of syphilis with mercury, none of my patients have shown the unusual phenomena which occurred in the case about to be reported.

My usual experience with the intramuscular injections of mercury for syphilis is that at the outset of the treatment the most marked reactions occur, but that after the patient has had a number of injections, about a dozen, these reactionary symptoms gradually diminish in intensity and number and finally disappear entirely. By reactionary symptoms I mean rise of temperature, pulse acceleration, increased headache, backache, and bone pains, occasionally restlessness, even delirium, etc., and do not refer to the ordinary symptoms of mercurialism, to wit, salivation, spongy gums, metallic odor, abdominal pain, gastroenteritis, etc.

The reactionary symptoms present after mercurial intramuscular injections, I have usually ascribed to two causes. First, to the presence in the patient's blood stream of myriads of dead spirochetes and their endotoxins; second, the presence in the patient's body of a foreign chemical, namely mercury.

If this drug (Hg) is continued over a very long period of time, then not only are there no reactionary symptoms, but a great number of patients fail to respond to the drug. That is, syphilitic manifestations which formerly cleared up readily with mercury fail to do so. In other words, for the time being the patient has developed mercury-fast spirochetes similar to the arsenic-fast organisms, as described by Ehrlich.

Under these circumstances it is advisable to discontinue the mercury for a time and administer arsenic in the form of salvarsan or neosalvarsan. This arsenical preparation will kill off many spirochetes that the mercury no longer could affect. It is probable that those remaining that are not killed by this new drug are so damaged and changed in their chemical affinity that on the readministration of mercury the original resistant strain of spirochete will then respond to mercurial treatment, with the result that syphilitic manifestations will again be dissipated.

In starting the patient with mercurial medication, it is advisable to commence with the minimum dose, increasing the same at each injection until the patient develops signs of mercurialism, then continue the treatment with a slightly smaller dose. This dose, of course, varies with different patients, depending on the weight, sex, age, and general robustness. The lower the weight the less dosage, unless the individual has a special idiosyncrasy to this drug, in which case one should give less than the average minimum dose. One usually gives a smaller dose to females, to the aged, and to the alcoholic. If an alcoholic is given a large dose at the outset of his treatment, it may put him into such a state of shock that he may develop delirium tremens. However, if in the alcoholic it becomes necessary to give a large dose of mercury, it is advisable to put him to bed and have him watched by a trained attendent for 24 to 48 hours. This may be necessary only for the first two or three injections. In addition this type of case should receive large doses of bromides.

The dose of salicylate of mercury is one-half to three grains given every fourth to seventh day. The details as to dosage for different patients have been gone into in order to bring out the marked exception in the case here reported. The following is the history of this unusual case:

H. R., age 27 years, single, male, commenced to have intercourse at 16 years, since which time has had intercourse weekly. Denies ever having had either gonorrhea or a chancre..

About one and one-half years ago he noticed a scaly eruption on his testicles and on right palm. This has persisted ever since. In addition he says that he feels "down and out." He tires very easily. Complains of anorexia. Has no bone pains or headache. At present the chief complaint is the palmar and testicular eruption and a feeling of general weakness.

Examination (Sept. 15, 1913) shows a papulosquamous circinate lesion in the center of the right palm, also a number of similar lesions on the scrotum, a few mucous patches on the lateral edge of the tongue, also one on the lower lip and scattered erythematous areas on the soles of both feet. No glandular involvement present. The diagnosis of secondary syphilis was made. Blood was drawn for a Wassermann test, and treatment was withheld until next visit.

Sept. 29. Wassermann of the blood was strongly positive. Some new papulosquamous lesions appeared on the penis. The patient received on this date salicyate of mercury, 4/5 grain, intramuscularly, with ung. hg. ammoniatum 5 per cent. to be rubbed into palms and scrotum.

Oct. 6. The patient feels stronger and much better generally; is not so easily fatigued. Lesions on the scrotum somewhat improved. Received salicylate of mercury, 1 1/5 grains, intramuscularly. Still continued the use of the white precipitate.

Oct. 20.—Says that for the past week the eruption on his testicles has disappeared. Feels stronger and more like working. Missed his treatment last week because he was too busy to call at the office. Is continuing the use of the white precipitate ointment. Received salicylate of mercury, one grain this day.

Oct. 27. A few new lesions have appeared on the penis and testicles. Complains of pain in the right ankle. On this date received 1½ grains of salicylate of mercury, intramuscularly, in addition to white precipitate ointment.

Nov. 5.—General feeling of well being. Salicylate of mercury, 1½ grains intramuscularly.

Nov. 10. Feels stronger than ever. The lesion on his lower lip is still present but improved. Injection given of 1½ grains salicylate of mercury.

Nov. 7. Some improvement in the lesions on the soles of the feet. The tongue and lower lip show additional improvement. Injection of 1¾ grains salicylate of mercury.

Nov. 24. Within an hour of his last injection he developed cold sweats and felt generally tired. This continued the entire night. The next day and during the entire week he felt all right. Received injection of 1 grain salicylate of mercury this day.

Nov. 24, Dec. 1, 8, 15, 22, 29. Received 1 grain salicylate of mercury each of these days without any reaction following.

On Jan. 5 and 16, 1914, he received 1½ grains each day, no reaction following.

Jan. 19. Received neosalvarsan 0.3 gram intravenously. Felt a little drowsy for one hour after the administration, otherwise there were no reactionary symptoms.

Jan. 26. Reports that no reaction occurred after reaching home. Gained 2 pounds during the week. All the lesions on the tongue, lips, and foot have disappeared. Feels very well.

Jan. 26, Feb. 2 and 9, 1914, he received an injection on each date of 1½ grains salicylate of mercury without any reaction following.

Before going into further details as to the subsequent history of this case, it would be advisable to give a summary of the salient features of the action of mercury up to this point. At the very first treatment, this patient received four-fifths of a grain intramuscularly and in addition mercury in the form of ammoniated mercury ointment, 5 per cent., the latter rubbed into the palms and scrotum twice a day. Yet no reaction followed. From that time on received weekly injections, varying from 1 to 1¾ grains. In spite of this dosage, he had but one reaction, and that was after a dose of 1¾ grains. In many instances he received weekly injections of 1½ grains, for three successive weeks, without any reactionary symptoms. I will now continue with the further progress of this case and we shall see what a marked change took place in the patient's tolerance for this drug. He stopped treatment for a period of eight months because he was obliged to leave town.

Oct. 6, 1914. The patient has returned because of recurrence of all of his symptoms, having had no treatment from Feb. 9 to Oct. 6, 1914, a period of about 8 months. Received a salicylate of mercury injection, 3/5 grain, this day.

Oct. 14. Had a well-marked reaction after the previous injection, manifesting itself by extreme degree of tiredness and weakness. This lasted 24 hours, after which he felt stronger than he did prior to his injection. Received an injection of 1½ grains this evening. Had a marked reaction within one hour after this injection. Manifested by cold sweats, vomiting, diarrhea, terrific headache, marked prostration, and

weakness. In fact, his symptoms were so severe that his family thought he would die. I saw him about 5 hours after his injection, and found him in a condition of extreme shock, with general pallor and a weak and rapid pulse. He remained in bed 24 hours. After which time he felt considerably improved, except that he complained of headache and dizziness, which persisted for an additional 24 hours. He was able to return to work on the third day.

Oct. 26. Because of the above-mentioned symptoms I reduced his injection to 1 grain on this date. In spite of this reduction, and in spite of the fact that he had received no injection for a period of twelve days, instead of his usual weekly injection, he again had severe symptoms, manifesting themselves within a few hours by frequent vomiting and a very severe headache.

Nov. 11. Because of previous symptoms from one grain dosage, I reduced his injection on this date to three-quarters of a grain. Within four hours he developed severe occipital headache, with constant "hammering in the head." He was unable to sleep all night. A dull headache continued all the week, in spite of the fact that there was a marked improvement in his specific lesions.

Nov. 18. For experimental purposes I again gave him three-quarters of a grain of salicylate of mercury. He again developed severe headache within three hours, but immediately took bromides and slept all night. Had no reactionary symptoms during the rest of the week.

Nov. 25. Since he complained comparatively little of his last injection, I thought I would try and see what symptoms would occur if I should slightly increase the dose. This day I gave him four-fifths of a grain instead of three-quarters.

Dec. 7. The patient returned to the office and reported that within four hours after the last injection he again developed so severe a headache that he was obliged to remain in bed. The pain this time not relieved by bromides, in fact, it continued without cessation for 36 hours. He also suffered with abdominal cramps, but no diarrhea. The note on my index card for this date was "This patient apparently has become most susceptible to mercury, and I am accordingly obliged to diminish his dose to one-half a grain." This I accordingly did.

During this entire period, from Oct. 6 to Dec. 7, 1914, while he was having such a hard time with his reactionary symptoms from mercury, he nevertheless showed a very remarkable diminution in his manifestations of syphilis.

Dec. 14. Reported that there was no reaction after the last injection of half a grain of salicylate of mercury. The patient's lesions have all disappeared. He again received but half a grain of the drug on this date.

Jan. 2 and Jan. 8, 1915. He developed no reaction from the previous half grain injections. So thereafter I decided to keep him on that dose, which he has been able to stand without any symptoms following.

Summary.—In studying this case carefully one sees that at the outset the patient was well able to take between one and one and one-half grains of salicylate of mercury without any symptoms. Not until one and three-quarters grains were given were there any signs of reaction. In other words, during the entire first period of treatment, that is from September 15, 1913, to February 9, 1914, the patient had absolutely no reactionary symptoms with a dosage varying from one grain to one and one-half grains.

Then came the second or middle period, a period of about eight months, during which the patient had no treatment. It was during this rest from treatment that the patient had a change to develop anaphylaxis. The pathologists have proved that certain foreign material injected into the body can, as a rule, be gradually increased in dosage up to a certain point and the animal or patient can remain at that dosage almost indefinitely; but cease the treatment (injection) for a period beyond three weeks and then recommence the injection and one will find that the body has developed hypersensitiveness to this foreign material. In the human body this may show itself by marked symptoms of anaphylactic shock, occasionally even death. In the lower animals with less resistance death is not at all infrequent.

After the eight-month period of rest, the patient returned for treatment. Immediately upon receiving his treatment he developed symptoms of hypersensitiveness to mercury. On his return I started him on three-fifths of a grain; this was followed by a marked reaction. I increased the drug at the following visit to one and one-half grains, and the patient went into extreme shock, although, as previously mentioned, the patient took this dosage eight months before without any symptoms following. I then cut down the dose to one grain and he still showed marked symptoms. I then diminished the dose to three-quarters of a grain, and within four hours the same manifestations occurred. I repeated the three-quarter of a grain dosage at the next visit with an identical result, showing beyond any doubt that this patient's tolerance for mercury had diminished more than 50 per cent. within eight months. Finally, seeing that even three-quarters of a grain could not be tolerated, I was obliged to cut down to half a grain, which was the only dosage he could take without a reaction.

Conclusions.—1. This case is reported because it is the only one I have ever had in which after a period of cessation of mercurial treatment an intolerance to the drug developed.

2. In spite of his intolerance to mercury he responded in a remarkable manner to the treatment.

3. My usual experience is that after a time the patient's tolerance for mercury is increased, while his response to treatment is diminished.

4. I do not know of a similar case reported in the literature, but in view of the fact that anaphylaxis to mercury may occur after the cessation and recommencement of treatment it behooves one to recommence with small doses, even if the patient has previously taken large doses without any reactions.

40 East Forty-first Street.

INDUCED PARANOIAC CONDITIONS.

By ARTHUR K. PETERY, M.D.,

NORRISTOWN, PA.

FIRST ASSISTANT PHYSICIAN, STATE HOSPITAL FOR THE INSANE.

In reviewing the various paranoiac conditions that frequently come to our attention, that type which might be called Induced Paranoia, that is, paranoid ideas induced by environment, seems to be of particular interest from the fact that it is being separated more carefully and the chances for recovery are much more favorable than were previously thought to be.

Formerly such cases were usually brought together under the general grouping of Dementia Præcox and the prognosis was rated as decidedly unfavorable, but the adoption of some of the later theories regarding the causation of these conditions has led us to look at these cases in a somewhat different manner and to be more optimistic as to their outlook for recovery.

Real paranoia is a form of psychopathic personality, and is a product of necessity arising from the irritations of life, and during the life of the individual these conflict with the other elements of their existence. These people are not in accord with their environment or fellow beings and are continually meeting with difficulties in maintaining their ideas. There is little or no effort on their part to adjust themselves to their surroundings, but there

is often a great tendency to bring other people to accommodate themselves to their views and opinions, and meeting the proper individual this effort is not difficult. An occasional example is seen in the originators of certain religious movements. The true paranoiacs are the incentives; they come in contact with persons of psychopathic natures, force their opinions on them, and are accepted by them as facts, thus bringing them into the fold of the type termed "induced paranoia." The originators are usually strong and active, while the induced are weak and hysterically inclined.

These patients, so long as the stimulus is present, retain these abnormal ideas, and their life and actions are practically under the control of the originator; but remove the stimulus or the originator and those induced can discard the ideas either to accept new ones or not, although during the activity of these induced ideas they are entirely irresponsible for their acts and frequently commit crimes, even murder as a religious sacrifice. These patients often need only such an impetus to make them start to misinterpret things and to carry them out according to their own ideas or the ideas of the originator. If these persons are placed under favorable environment, free from conflicting stimuli, and are given a little assistance along the proper channels they frequently discard the ideas and return to their usual or normal condition.

The following case was one of particular interest:

Family History.—The father was of temperate habits; had been active in church work at one time, but for the past fifteen years took no special interest in religious matters. The mother showed no unusual mental or religious tendencies. No history of any mental diseases elicited.

Personal History.—Was the sixth child in a family of seven; attended school during the winter months from six to fourteen years; learned poorly and had to study hard to gain what the other pupils acquired easily; he often cheated and copied from others. Never received any serious injuries. Had hay fever at intervals since sixteen years of age; used alcoholics and on several occasions to excess. Married at the age of twenty-eight years; domestic life was happy. Worked as a farmer until eight years before his admission, when he began working in the cement mills, gradually advancing to the position of master mechanic and earning about $125.00 per month. Was confirmed in church at the age of sixteen and at twenty-four years was a teacher in the Sunday School and took a very active interest in church work. Later he became less attentive and attended irregularly. Was always inclined to go to extremes in everything.

At the time of his trouble he was about thirty-five years of age and was admitted to the State Hospital at Norristown, June 5, 1908, from a county prison, where he had been held on the charge of murder of his niece.

The records state that in January, 1908, he was out with some friends when one of them mentioned that a common friend had been converted and had "changed greatly for the good." After thinking about it he became dissatisfied with his own spiritual condition, sought out the converted one, talked it over with him and was advised to read his Bible; this he proceeded to do at every opportunity and to the extent that in March, 1908, he obtained two weeks' leave from his work to continue his reading.

About the middle of February, 1908, he received what he thought was his first sign from God and about March 15, while reading his Bible he looked out of the window and saw the "Angels of Light," which he described as "balls of fire" moving about and passing in various directions; also during the day the evil spirit appeared to him three times and tried to tempt him.

He then interested his wife, as well as his brother-in-law, in these new found ideas and during April they frequently held religious meetings, but without any violent outbreaks. However, during the latter part of April the brother-inlaw, his wife, and child came to spend several days at the patient's home, which time they devoted to religion, and each had frequent visions, in fact, was seemingly trying to out do the others. They dined irregularly, the spirit telling them when to eat, etc. During this time the child played about the room and occasionally brought leaves and other trifles to them. They developed the idea that the child was possessed of a devil and that these offerings were temptations from the devil to attract them from their religion. The child continued to annoy them until finally the patient pushed the child to the floor, holding it by the neck to drive out the devil, and in a short time the child was strangled to death. The impulse came to kill, drive out the devil, and thus send the child to Heaven instead of Hell. The next day, when arrested, the patient was still having visions, but was much quieter generally. In prison he showed little of his former excitement.

The hospital records state that on admission the patient talked readily and was mildly exalted spiritually; was positive that he had done no wrong and maintained this attitude until the latter part of December, 1908, when in conversation he stated he had begun to realize that he had "allowed his ideas to take too deep a hold on him" and that he had gone entirely too far. Where the impulse came to kill came from, he did not know, but was willing to admit that it might have been due to the fact that he was temporarily unbalanced mentally.

From this time on a marked improvement was noticed. He worked about the wards and also took charge of some incubators, being successful in the raising of chickens. In January, 1911, when before the staff, he said that when admitted he felt he could not criticise himself for his actions and that he felt justified in doing what he had done, but that about a year after his admission he began to have some doubt as to his actions being proper, but was not sure and would not admit it for that reason; he was unable to tell what changed his opinion, except that since being here and seeing insanity, he felt he might have been insane.

He was discharged February 1, 1911, into the custody of the sheriff, who returned him to the Courts, and who eventually discharged him. He is now living outside, making a fair living, but is rather erratic.

During this writing it has been noticed in the newspaper that a brother of this patient committed suicide by inhaling gas, while out on bail. He had been arrested on charges of conspiracy to kidnap a four-year-old son of his wife's niece, with whom he had eloped, while his own family were in California. It is probable that there was also an abnormal element in this brother.

Another type of induced paranoiac conditions is found in the Imprisonment Psychosis. This occurs in persons of psychopathic natures who are confined or prevented from leading the lives to which they are accustomed; they find they are unable to accommodate themselves to this state of affairs and finally to recompense themselves, develop a psychosis of degrees varying from depressions to active hallucinations. These conditions usually disappear quite promptly when the person is placed under more favorable circumstances either by removal to a hospital or by allowing them more privileges in the prison.

The following case is a clean-cut example of this type:

In the family history, the father at the age of seventy-two years is an excessive user of alcoholics; the mother has a harelip and is "tongue-tied." No definite history of any mental disease can be found.

The patient, a white male, now about forty-one years of age, attended school from his sixth to eleventh year, but never got along well. Worked in a rolling mill up to his thirtieth year, after which he became a telephone lineman. At the age of twenty-one years had a severe attack of pneumonia and typhoid fever; was confined to bed for twenty-two weeks, following which his mother thought he was not as keen mentally as prior to his illness. At the age of thirty years he married and five children resulted from this union.

One child died during infancy, another of convulsions and a third at the age of one week from a "brain abscess." He used alcoholics and at times to excess. Wassermann reaction of blood positive.

Nine years prior to admission he was arrested for striking an officer while intoxicated and served a sentence of one year. Fourteen months before his admission he was arrested for stealing coal, tried, and sentenced to two years. After serving fourteen months he developed mental symptoms and was committed to this hospital, May 28, 1913.

On admission he was depressed and extremely apprehensive; believed that he was going to die and that he was brought here for that purpose. His attention was held with difficulty; admitted the presence of hallucinations of hearing; stated that frequently he heard the warden at the prison talking about him; that he also heard other voices speaking ill of him; declared that the warden and keepers placed poison in his food and abused him without cause; that they refused to obtain a lawyer for him when he was unjustly convicted of stealing coal; also he thought his wife was untrue to him while he was confined in jail.

Under hospital treatment and routine he showed a progressive improvement both physically and mentally. In five months he made a gain of thirty-four pounds in weight. His hallucinations disappeared, but he was suspicious and retained ideas of poisoning. While he denied these, still he was frequently seen picking his food apart and carefully examining it before eating.

On October 25, 1913, he obtained a key and made his escape from the hospital. On January 2, 1915, he was located and returned. While away from the hospital and leading the life to which he was accustomed he regained his normal mental status and on his return talked well, realized his condition, and said that on his first admission he was "pretty sick" and that "his voices and ideas" were the result of his illness; no hallucinations or delusions could be elicited.

January 13, 1915, he was returned from the hospital to the prison to serve out his unexpired sentence. However, when seen a month or so later in the prison he was again becoming apprehensive and developing mental symptoms. The keepers expressed the fear that they would have to return him to the hospital, for he was "getting off again." However, on advice and by a special effort on their part they were able to tide him over to the completion of his sentence.

Another class of cases very closely allied to this type of psychosis is the Psychosis of the Deaf and one which seems to be becoming more prominent; at any rate we are seeing more of these cases at this time. These people are really isolated or imprisoned to a certain extent from their surroundings and being of a psychopathic makeup, with a sense of embarrassment from their affliction, find satisfaction by making explanations to themselves which they magnify until they have developed a psychosis.

Very frequently there is some pathological condition of the ear present that causes a roaring or buzzing and which these cases are prone to interpret as "voices"; they become suspicious, people talking together are surely discussing them, and they feel that they are always the object of conversations. This usually leads to a depression; they think they are being watched; that derogatory remarks are being made about them until finally in order to escape these torments they attempt violence or self-destruction. The following case is rather typical:

Family History.—The father was shot in the head during the Civil War and died at the age of fifty-one years in an insane asylum. A maternal nephew is now in this hospital suffering from paresis.

Personal History.—Patient is a white male about forty-six years of age; his early life was uneventful; attended school from his sixth to twelfth year and learned well. Was a leather finisher by occupation and worked steadily up to several months before his admission.

At the age of seventeen years had typhoid fever, suffering three relapses, and was confined to bed for four months. During his convalescence he became totally deaf and remained so. Two months prior to his admission he first complained that he heard voices which told him people were trying to "put up a job on him," and that his fellow workmen talked about him; he then attempted suicide by drinking iodine, but prompt treatment frustrated his attempt. Several days later he twice attempted to throw himself before moving trolley cars; was picked up by the police and taken home. The next day on the advice of these voices he attempted suicide by cutting his throat with a razor; he was immediately taken to a general hospital and as soon as he had recovered sufficiently he was committed to this institution.

On admission he was depressed; answered questions slowly; his orientation and memory showed no impairment. He admitted the presence of hallucinations, and these hallucinations and the resulting depression were his chief mental characteristics. These voices threaten, call him vile names, and abuse him no matter whether he is playing cards or working. When they are annoying him more than usual he will complain to the physician; occasionally he can be partly convinced that these "voices" are due to his diseased ear condition. This will seem at times to satisfy him, but again this argument will have no effect against his statement that "they are so real to me." He has been in the hospital since 1912 and shows no definite mental deterioration at this time. His memory is good; is well versed in current events; is a good worker and careful in his habits.

This case is interesting from the fact that the patient is able to be convinced up to a certain point, but is then overwhelmed by his hallucinations and lapses back into his former condition.

If the physical condition of these cases is such that it can be cured or even improved by treatment the mental outlook for the patient is good, but if the hearing is completely destroyed the outlook is bad. Occasionally such a patient might be benefited by analysis or by education to the fact that his ideas are developed as a result of his physical disability.

The above cases have been selected from the records of this hospital as typical of the various phases of induced paranoia. Of course, the symptoms may vary in intensity from a few vague persecutory ideas to an elaborate system of delusions and active hallucinations, but the taking into consideration of the entire history of the case and the underlying causes may help to reduce the number of unfavorable prognoses.

DEVELOPMENT OF LITHOLAPAXY DURING SIXTY-TWO YEARS FROM CIVIALE TO BIGELOW.

By CHARLES AUBREY BUCKLIN, M.A., MD.,

GLASGOW, SCOTLAND.

THE first step in the establishment of this operation was made by Civiale of Paris in 1817, who commenced to experiment on lithotrites during that year. His first publication regarding a successful result with the operation of lithotripsy was in 1824, and it produced a great sensation among the surgeons of the world. The second step regarding this operation was the publication of Civiale's ideas among English surgeons who took kindly to them.

Civiale's publication of his successful case of treatment by crushing the stone in the bladder incited John Weiss, a skilled instrument maker, to invent and manufacture in London during the year 1824 a lithotrite, which for large instruments is, in the author's opinion, superior to the one of Civiale's construction. Thanks to Weiss' instrument, members of the English profession were led

to consider lithotripsy with favor; although French surgeons still consider Civiale's construction the best for light instruments, while recognizing the Weiss-Thompson construction as the best for heavy instruments.

Brodie used the Weiss lithotrite in cases that were reported in "Lectures on Diseases of the Urinary Organs" in 1833, Second Edition, page 318. In the spring of 1825 the spring saw was used in the bladder for the reduction of stones to fragments, but without any decided success.

In 1830 the Weiss screw lithotrite was shown to Heurteloup, who within a few months brought out his instrument, in which a hammer was substituted for the screw of the Weiss instrument. In 1833 Brodie reported in the *London Medical and Surgical Journal* cases in which he had used the Weiss lithotrite successfully. In 1833 the Weiss lithotrite was modified so as to act with the screw or the hammer. In 1834 Fergusson published a description of his lithotrite, which was simply that of Weiss, save that it worked with a rack and pinion instead of a screw and was less efficient from a mechanical point of view.

In 1834, on October 7, Brodie wrote to John Weiss the following: "It must be between nine and ten years since you first showed me a lithotrite that you made for the purpose of crushing calculi in the cavity of the bladder by means of a screw. I have not the slightest doubt but the credit of having contrived a lithotrite for crushing calculi in the bladder by means of a screw belongs to you."

In 1834 Anthony White of the Westminster Hospital stated in a letter to John Weiss that "the first of your lithotrites shown to the surgeons of London was in the year 1824." Thompson became intensely interested in lithotripsy in 1863, and, after inspecting Civiale's, Weiss', and all the lithotrites then in the market, he made certain suggestions regarding what it was necessary for lithotrites to possess in order that they might become popular. Thereafter the Weiss lithotrite was called the Thompson instrument, not because of any original suggestions made by Thompson but because it was considered politic to change the name.

The third step was the invention by Bigelow of litholapaxy at Boston in 1879; his first publication appeared in that year. Two lithotrites purchased at Paris in the spring of 1878 were laid away because the author became disgusted with the lack of success attending lithotripsy in relieving the irritation of the bladder which was due to the fragments of calculi remaining within its cavity. One of these lithotrites was Civiale's and the larger one was Thompson's instrument. They were not brought out again until 1882, when the author commenced to practise the operation of litholapaxy by Bigelow, which he has followed since this last date, usually relieving the patient of every trace of an irritable bladder by one operation.

The evacuating apparatus purchased by the author in 1882 is known as Bigelow's first evacuating apparatus; there are now a second and a third evacuating apparatus by this author for evacuating the fragments of crushed stone from the bladder, also several unimportant imitations of Bigelow's instruments, all of which the author has seen used in the hands of other men. The first instrument of Bigelow's is the most perfect instrument ever devised for removing the crushed fragments of stone from the bladder. There are not any breaks in this bag which exhausts this instrument except-ing at the two extremes, where there is little or no motion produced by closing the bag. In this instrument it is much easier to produce a bag that will not continually leak than in any of the newer forms of this instrument. There is not a cock or valve attached to the apparatus, as there is in some of the newer forms of evacuating instruments. Its extreme simplicity is its merit. The separation of the fragments of stone from the bladder is more rapidly accomplished by the first instrument recommended by Bigelow than by any other differently constructed instrument.

The special advantage of the first instrument of Bigelow's is a lengthy piece of tubing which connects the bag with the proximal end of the urethral tube, which enables the operator to appropriate the fullest effects of gravitation in separating the fragments of stone from the urine or fluid in the bladder by lowering the bag to the lowest possible position while the instrument is being used for the above purposes. It certainly has advantages over all other forms of evacuators in this separation act.

Browne of London, in his eulogy of the late Clover published in the *Lancet* on May 12, 1866, attempts to place his name first regarding the aspiration of foreign pieces of calculi from the bladder. Dr. Flemming of Dublin published in the *Dublin Journal of Medical Science* in February, 1866, a device similar to Clover's for evacuating fragments from the bladder after lithotripsy, the only difference being that in Clover's instrument the catheter projected into the cylinder that was intended to collect the fragments, which Clover claimed was the only difference between his satisfactory instrument and Flemming's unsatisfactory instrument. It will be observed that in both of these instruments there was an uninterrupted wash through the receiving chamber every time that the pumping bag was squeezed, and that neither of these instruments could have been satisfactory for the purpose it was intended to fill.

The perfection of the operation of litholapaxy was published by Bigelow of Boston in his methods of operation. His work is now known all over the world and is generally appreciated. His first instrument was perfect, as is confirmed through the removal, by a man of Browne's experience, of the valves within his evacuators, and thus reducing them to the simple first instrument of Bigelow.

The mechanical instincts of every practitioner of surgery should condemn Clover's apparatus as not being of any practical value in removing the fragments of stone from the bladder after a crushing operation. Thompson used Clover's device long before the apparatus of Bigelow was published, and abandoned it; suffice it to say that he never abandoned Bigelow's device.

After the two lithotrites described in this paper Bigelow's device is necessary to complete the operation.

It may be interesting to compare the operation as performed with Bigelow's device with Civiale's and Thompson's attempts to rid the suffering patients of the annoying bladder irritations occasioned by the presence of fragments of stones within this organ.

It is a common experience to see the patient entirely relieved of his irritable bladder by a single operation of litholapaxy, a result never obtained from the operation lithotripsy in the practice of Civiale or Thompson.

One-fifth of a grain of morphine is given to the

patient every twelve hours for the first four days after the operation, and this is followed by a tablespoonful of heavy magnesia at the close of the fifth day. No unpleasant symptoms accompany this operation if the above instructions are strictly followed.

Stricture of the male urethra is a frequent complication which has to be obviated before the patient submits to an operation for stone in the bladder by litholapaxy.

The male urethra should always be examined for determining the normal caliber of this canal. The Otis or Kollmann urethrometer has invariably been used by the author for the above purpose. The distended portions of these instruments should always be covered by a rubber cap for the purpose of preventing the mucous membrane of the urethra from falling between the distended springs of the instrument. Both the instrument and the cap should be sterilized every time before being used. Should a stricture be encountered, the author's portable quadruple-action crutch for exposing the perineum should be used and the strictured portions divided by external urethrotomy (MEDICAL RECORD, January 4, 1913), so that a tube of the normal caliber of the urethra may be readily introduced after the meatus has been properly stretched to receive this urethral tube.

The unscrewing of a lithotrite the bill of which has been hooked into the meatus is the handiest way of stretching the meatus to receive this properly sized urethral tube for performing litholapaxy. When the crutch is used while treating a stricture of the urethra it is desirable that it be retained in position during treatment for the stone.

23 MANSION HOUSE ROAD.

ANOMALOUS CASES OF MASTOIDITIS.

BY CHARLES B. BRODER, A.B., M.D.,

NEW YORK.

INSTRUCTOR IN LARYNGOLOGY, POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; ADJUNCT LARYNGOLOGIST AND OTOLOGIST, CITY HOSPITAL; VISITING OPHTHALMOLOGIST AND LARYNGOLOGIST, PEOPLES' HOSPITAL.

THE difficulties that beset the surgeon in a mastoid operation depend a great deal on the anatomical configuration of the mastoid process and the relationship of the structures in intimate contact with it. In the average temporal bone the mastoid process is cellular in character, of pneumatic, diploic, or mixed type, and the position of the sigmoid sinus and of the floor of the middle fossa to the mastoid process is more or less definite.

The following cases of mastoiditis show anomalies in the anatomical structure of the bone, abnormality in the position of the sigmoid sinus and an atypical character of osseous involvement.

CASE I.—H. W., age 21 years, was admitted to Peoples Hospital March 29, 1916. Patient complained of a continuous discharge from the left ear for last six months following a severe attack of influenza. For a few weeks previous to admission, the discharge was more profuse, and he had severe pains on the left side of the head. Physical examination showed abundant pus in the external canal, and a large perforation in the anterior inferior quadrant with prolapse of the posterior canal wall. The functional test revealed diminished hearing for voice and whisper in the left ear, the other ear being occluded by the Barany noise apparatus. Marked tenderness over the antrum was elicited on pressure. Diagnosis: Subacute purulent otitis media with complicating mastoiditis.

A simple mastoid operation was performed, with curettage of the Eustachian tube through the perforation in the drum membrane. On removing the cortical layers of bone the sinus was found to lie well forward and superficial, the knee impinging on the supromeatal triangle area, and coming in contact with the posterior canal wall. In fact, the sinus completely filled the mastoid process. This position of the sinus rendered the exposure of the antrum difficult and tedious. No other mastoid cells were found. The necrosis had involved the tegmen antri with exposure of the dura, which was found covered with granulations.

The point of interest in this case was the extreme forward position of the sigmoid sinus, with the rudimentary development of the mastoid, and the absence of all cellular structure. The mastoid process was of the kind commonly seen in infants.

CASE II.—E. H., age 20, gave a history of a persistent discharge from the left ear, with deficient hearing for the past five years. At the time of admission to the hospital, January 23, 1916, an otoscopic examination showed a chronic purulent otitis media, associated with all the symptoms of an acute mastoiditis. The lower half of the drum was gone, the discharge was profuse, and there was marked tenderness especially over the upper part of the mastoid.

On account of the long and narrow condition of the process, with the possibility of a forward sinus, chiseling was begun from the suprameatal spine downward, along the anterior border and continued in a groove until the antrum was reached. Further curettement revealed the sinus well forward and the middle fossa plate unusually low; in fact, it was considerably below the linea temporalis. No necrosis was found anywhere except in the zygomatic region, where the cells were completely broken down. The bridge between the tympanum and antrum was removed and the posterior canal wall lowered on a level with the external semicircular canal. The incus and malleus were found intact and were left in. The attic was cleaned out, and the Eustachian tube curetted through the posterior opening. The retroauricular incision was sewed up almost completely, a small opening being left at the lower end for packing and drainage.

The interesting points in this case were the localization of the infection to the zygomatic cells, the rest of the process being free from inflammatory changes, and the unusually low position of the dura which called for exceptional care to avoid injuring it.

CASE III.—J. W., 21 years old, was admitted to Peoples Hospital December 10, 1915, with a history of a discharging left ear for the last three months. Examination showed a subacute exudative otitis media associated with a purulent condition of the mastoid cells. A mastoid operation was performed. A perpendicular incision was made through the soft tissues down to the bone and the flaps retracted. Directly underneath the periosteum the bony wall of the sigmoid sinus came to view. This extreme superficial position of the sinus rendered it liable to injury if a secondary horizontal incision would have been made. An anatomical anomaly of this kind contributes greatly to the accidents of mastoid surgery. The cells were found filled with detritus and granulations, necessitating a thorough exenteration. Healing was uneventful and rapid.

CASE IV.—P. G., age 70. Operated upon October 29, 1915.

This case was fully reported in a previous publication, the case history showing a chronic purulent otitis media with a latent suppurative labyrinthitis and a complicating mastoiditis. It is mentioned in the present instance as illustrating the extreme development of cells in the temporal bone. The cells were widely distributed, surrounding the sigmoid sinus and extending far back into the occipital bone, high above the linea temporalis into the squamous portion, deep down around the pyramid of the petrous portion, and showing marked development at the zygomatic region extending upward and forward as far as the apex of the glenoid fossa.

This case together with the one with the rudimentary mastoid shows the two extremes in the cellular development of the adult temporal bone. Com-

plete removal of all the cellular structure exposed a very extensive area.

Case V.—M. S., 40 years old, was admitted to my service at the Peoples Hospital May 26, 1916, with the history of a discharging ear for the past three weeks. Careful inquiry failed to show any previous ear trouble. Examination gave all the signs of an acute purulent otitis media and mastoiditis. The mastoid process was exceptional large size, broad and flat. Tenderness elicited only over the emissary vein. The main subjective symptom was a severe headache, especially at night.

On operating, the mastoid process was found dense and compact, showing complete sclerosis such as often occurs in a chronic purulent otitis with involvement of the mastoid cells. In this case, previous aural infection was ruled out by the history. With the exception of the antrum there was complete absence of cellular tissue, the mastoid space being occupied by massive bone. The sigmoid sinus was situated deep, and far back from the external meatus. On exposing the antrum a slight trace of muco-pus was found, but elsewhere there was no visible inflammatory involvement. The region at the posterior root of the zygoma, and the tip, also the space around the knee of the sinus, were cleaned out and searched for necrosis, without any trace being found. It was finally decided to close the wound, when on further curettement free pus oozed out from the space between the upper surface of the bend of the sigmoid sinus and the floor of the middle fossa. This area was now thoroughly cleaned out, leading to a denuded dura and sinus, the two surfaces almost coming in contact. A smear of the pus on examination showed the pneumococcus.

The points of value in this case were the compact character of the interior of the mastoid process, in an acute otitis media, with the absence of any cellular structure, also the localized point of degeneration, far removed from the source of infection. Except for the completeness of the operation, this localized area would have been overlooked and might have caused serious consequences.

The anomalous conditions enumerated in the above cases show the necessity of preparation and care in mastoid surgery. The examination of the mastoid process as to its shape and size will often give an indication of the location of the sigmoid sinus.

Skiagraphy offers valuable information as to the site of the sinus and of the floor of the middle fossa and may locate deep and hidden points of infection.

The case of P. M. shows the necessity of the complete operation in mastoiditis and every otologist is acquainted with numerous instances where exenteration of apparently normal cells led to and revealed unsuspected areas of necrosis.

221 Second Avenue.

A CASE OF GASTRIC ULCER.

By J. RUSSELL VERBRYCKE, JR., M.D.,

WASHINGTON, D. C.

ATTENDING GASTROENTEROLOGIST TO THE WASHINGTON ASYLUM HOSPITAL.

The following case is one of a very common disease, but with a number of unusual and most instructive features:

Mrs. J. R., æt., 47, consulted me in March, 1914, complaining of epigastric pain running around the abdomen to the back, heartburn, and constipation. She was afraid to eat. The symptoms used to come on two hours after meals, but of late have appeared at various times and were relieved only partially by alkalies. Her symptoms had started fifteen years before. Twelve years before she had two profuse hemorrhages and was treated for ulcer, remaining in bed some weeks.

Abdominal examination showed the stomach to be hypertonic. There was slight general tenderness with a point of greater tenderness localized midway between the naval and gall-bladder region. Examination of the stomach contents showed free HCl 60, and a total acidity of 74. There was faint occult blood in the stool.

She was put on an ambulatory treatment for several days without improvement. She was then radiographed and a marked spasmodic incisura was seen extending half way across the stomach and opposite a tender spot on the lesser curvature, half the distance from the cardia to the pylorus. Physical examination at this time showed marked tenderness and irritability of the stomach and she was advised to have an operation without delay.

She determined to await advice from her son who was an intern in a Western hospital and just one week later she was seized at four in the afternoon with terrific pains in the abdomen, chills, and fever. I saw her at 10 o'clock the next morning at which time there was great general abdominal tenderness but no rigidity. There was slight fever, a pulse of 90, nausea, but no vomiting. A subacute perforation was suspected. Morphine, gr. ¼, was given and everything stopped by mouth.

At 1 P. M. her condition was about the same except that the pulse had gone to 100. Leucocyte count at this time was 4,400. She was taken to the hospital and Dr. L. H. Reichelderfer saw her with me at 5 P.M. Her temperature on admission was 99.8° and was steadily rising, while her leucocyte count had fallen to 3,200. We decided to watch her carefully and try to hold off operation until the arrival of her son, but at 10 P. M. her condition seemed worse with temperature of 101.8°, pulse of 110, and a white blood count of 2,850 with 73 per cent. polymorphonuclears, so that we were afraid to delay further in spite of the absence of much rigidity.

Operation by Dr. Reichelderfer revealed a mass of fresh adhesions on the lesser curvature about two inches from the pylorus and beneath these a blood red, congested area. The peritoneal covering of the whole stomach was somewhat congested but this spot was fiery in color. Careful palpation showed that there was no thickening to indicate induration and palpation alone would not have located the ulcer. It had progressed partly through the peritoneal coat and there was probably a pin hole perforation, as the gross appearance was such, although the opening could not be found. The ulcer area was turned in and a gastroenterostomy performed. The whole stomach was carefully examined for other ulcers or scars and none were found. The temperature dropped at once to normal and the leucocyte count rose, showing plainly cause and effect. Recovery from the operation was uneventful.

This is one of the most instructive cases of ulcer I have ever had, and I will emphasize several points. There is such a thing as a chronic non-indurated ulcer or a non-indurated surgical ulcer, some writers to the contrary notwithstanding. This same ulcer had undoubtedly existed for fifteen years, as periods of remission were comparatively short during that time and no scars of other ulcers could be found. Such a non-indurated ulcer may progress to hemorrhage (three years) and to perforation (fifteen years).

It is often difficult and at times impossible for the surgeon to find a known ulcer. Touch is usually depended upon. No thickening could be felt in this case and had it not been for the unusual reddening it would not have been possible to have found it.

In view of the foregoing, a medical diagnosis based on signs and symptoms, but not symptoms alone, is of greater value than a surgical diagnosis made at the time of an exploratory incision. Therefore, every patient should have a complete examination and localization of the ulcer before operation, when conditions permit, in order that the surgeon's task may be easier. The ulcer is not always under the tender spot. No ulcer is safe from dangerous complications. There may be trouble in a month or not for many years.

Although perforation often develops without warning it is occasionally possible, as in this case, to determine that the ulcer is in a very irritated condition a week before perforation.

The rising temperature and falling leucocyte count in this case indicated very poor resistance. One of the counts of 4,400, 3,200, and 2,850 was the lowest that I have ever encountered. It was corroborated by several counts. That the low count was directly due to the patient's condition is evidenced by the fact that it arose immediately after operation.

I have maintained several of the views emphasized above for some time and have a number of cases illustrating each, but it has never been my good fortune before to have one patient presenting proof of so many of them.

THE ROCHAMBEAU.

Medicolegal Notes.

Privileged Communication Statute Does Not Apply to Will Contests.—The South Dakota statute, Code Civ. Proc., Sec. 538, declares that a physician or surgeon cannot without the consent of his patient, be examined in any civil action as to any information acquired in attending the patient, which was necessary to enable him to prescribe or act for the patient. Section 12 defines an action as an ordinary proceeding in the court of a justice, by which a party prosecutes another party for the enforcement or protection of a right, the redress or prevention of a wrong, or the punishment of a public offense. The South Dakota Supreme Court holds that, in view of Section 486, excluding testimony as to transactions with deceased persons in both civil actions or proceedings by or against executors, etc., and the limitation in Section 538 to civil action, a will contest is a proceeding and not a civil action, and a physician of the testator may testify as to the latter's incompetency; for the statute making physicians incompetent, being in derogation of the common law, should be strictly construed.—In re Golder's Estate (S. Dak.) 158 N. W. 734.

"Practice of Medicine"—Wisconsin Law.—In proceedings for practising medicine without a license it was contended that the provisions of the Wisconsin statute, Section 1435, Stats. 1913, arbitrarily attempt to define what is to constitute the practice of medicine and surgery, and condemns practices which do not, in substance, constitute the practice of medicine and surgery, and hence deprive persons of rights guaranteed them by the State and Federal Constitutions. The defendant claimed that the provision of the section penalizing all persons who shall append to their names the words or letters, "Doctor, Dr., Specialist, M. D., D. O., or any other title, letters, combination of letters or designation which in any way represents him or her, or may tend to represent him or her, as engaged in the practice of medicine, surgery, or osteopathy in any of its branches, or who shall for a fee or for any compensation of any kind or nature whatsoever prescribe or recommend for like use any drugs or other medical or surgical treatment or osteopathic manipulation, for the cure or relief of any wound, fracture, bodily injury, infirmity or disease," is an arbitrary classification as medical and surgical practitioners of persons who are not necessarily engaged as such practitioners, and thus deprives them of the liberty to do these things, contrary to their constitutional rights. The court said the contention overlooked the fact that the use of the words or titles so appended to a name is denounced by the law whenever they represent, or tend to represent, the person as a practitioner of medicine, surgery, or osteopathy, or if he as such a practitioner does anything by way of treatment or gives a prescription for a fee. All the prohibited acts are limited to persons who in fact do these things as practitioners of medicine, surgery, or osteopathy.—Piper v. State (Wis.), 158 N. W. 319.

Injury as Cause of Typhoid.—In an action for personal injuries by being run down by an automobile, the Wisconsin Supreme Court holds that testimony of a physician that typhoid fever may be caused by polluted water or food, but that in his opinion there was a connection between the plaintiff's injury and his contracting typhoid, is insufficient to warrant a finding that the illness was caused by or had any connection with the injury.—Slack v. Joyce (Wis.) 158 N. W. 310.

X-Ray-Picture Evidence. — The Michigan Supreme Court holds, in an action for personal injuries, that an expert witness will not be allowed to testify as to what an *x*-ray picture showed, in the absence of the picture. The picture is the best and only evidence of what it did or did not reveal, and while it is matter of common knowledge that the correct reading of such a picture is a thing for experts, there can be no proper cross-examination of an expert interpreter in the absence of the thing interpreted.—Jolman v. Alberts (Mich.) 158 N. W. 170.

Practising Without License Not a Joint Offense.—Section 8315 of Missouri Revised Statutes, 1909, makes it an offence to practise medicine without a license, and under Section 8313 the license to practise medicine must be procured by individuals. The Kansas City Court of Appeals holds that the joint participation in an act of treatment constitutes no joint offence, but may constitute one or two offences according to whether one or both of the parties is without a license. The failure to procure a license is necessarily an individual and not a joint matter, so that a conviction of two jointly indicted for practising medicine without a license when the jury fixed the punishment at $50 for both defendants, and the court entered judgment for $5 against each, was reversed.—State vs. Hendricks (Mo.), 187 S. W. 272.

Revocation of Licenses—Advertising Cure of Incurable Diseases.—In a prosecution for revocation of a practitioner's license for wrongful advertising it appeared that the defendant advertised his ability to cure many diseases either wholly incurable or nearly so. The Washington Supreme Court held that to prove the offence of wrongful advertising denounced by the statute moral turpitude need not be shown. But it was also held that it is not merely unethical but immoral to get money from the poor, the simple, or the ignorant by advertising the cure of what is incurable, and the courts will call that incurable which the present stage of knowledge so pronounces. Nor is it incumbent on the State to show whether there was any actual harm done to any one through the defendant. The statute aims to protect the purse as well as the health from quacks, and the other burden, if cast on the board, would, through the many conflicting and contributing influences on the health of patients, make proof exceptionally difficult. — State Board vs. Jordan (Wash.), 158 Pac. 982.

Practising Without License. — The Washington Supreme Court holds that a system of "Suggestive Therapeutics," in which the defendant indulged in prayers, laying his hands on the patient, manipulating the muscles and nerve controls, and claimed cures, is "practising medicine," and the name and method a mere subterfuge to escape the requirement of license.—State vs. Pratt (Wash.), 158 Pac. 981.

Expert Testimony as to Malpractice in Adjustment of Splints.—In a malpractice action it appeared that the injury to the plaintiff, a child, was due to undue pressure caused by adjustment of splints on a broken arm by the defendant not allowing for the usual swelling accompanying such cases. It was held that the question as to whether the omission to properly adjust the splints constituted negligence was one for expert testimony.—Priestley vs. Stafford (Cal.), 158 Pac. 776.

Chiropractors Require Certificates in California.—A person who was a teacher and demonstrator of a chiropractic system in a chropractic school and treated afflicted subjects who sought and received treatment at his hands free of charge was held guilty nevertheless of practising a system and mode of treating the sick and afflicted without possessing a certificate of the California State Board of Medical Examiners.—People vs. Oakley (Cal.), 158 Pac. 505.

Practising Without Certificate—Gratuitous and Emergency Services.—In an action for practising a system of chiropractics without a certificate it is held that the California statute covers such practice whether the service is compensated or gratuitous. Where persons had previously had the attention of physicians, their ailments being more or less chronic, and the defendant's services being sought to some extent as a last resort, and after other practitioners had failed to afford relief, the treatment rendered by him could not be classed as emergency services not prohibited by the medical act.—People vs. Vermillion (Cal.), 158 Pac. 504.

Users of Narcotics as Witnesses. — The habitual use of opium, morphine, cocaine, or other like narcotics, as it tends to impair the mind, destroy the memory, and pervert the moral character of a witness, may be shown for the purpose of affecting his credibility or the weight that should be given to his testimony, but is not ground for the exclusion of his testimony unless it satisfactorily appears that he was under the influence of the drug to such an extent that he was unbalanced when a witness. State vs. Fong Loon, Idaho Supreme Court, 158 Pac. 233.

CAROTID TUMORS.

THE first exhaustive American paper upon this subject was contributed in 1906 by Keen and Funke (*Journal of the American Medical Association*, 1906, XLVII). By including all cases found by a careful search of the literature, they were able to present reports of 29 cases—27 in the living, and two that had been discovered at autopsy. After this time sporadic case reports appeared in medical journals in various parts of the world so that seven years later, when Callison and MacKenty (*Annals of Surgery*, December, 1913) had occasion to report a case and reviewed the literature, it was found that theirs was the thirty-first case that had been reported since Keen and Funke published their article, thus making a total of sixty. The latest addition to the literature of this subject is contributed by Randolph Winslow (*Annals of Surgery*, September, 1916), who brings the number up to 72 by reporting in detail two cases (one of which was operated upon by himself, the other by his colleague, Dr. A. M. Shipley) and adding brief references to ten other cases, reports of which he had found in the literature since the publication of Callison and MacKenty's article. We may add that the list is still incomplete since we know of at least one case (F. S. Mathews, *Annals of Surgery*, May, 1914, page 752) that is not included in Winslow's references. It is thus seen that more cases have been reported in the last decade than Keen and Funke were able to collate in 1906 from all previous literature. Whether this should be accredited to the greater skill of the present generation of surgeons or to the more general study of pathological specimens in recent years is a question; for certainly there seems to be no good reason why there should be an actual increase in the percentage of individuals having carotid tumors, as the above statistics would seem to indicate.

The carotid body is briefly described by Winslow as a small structure situated at, or just posterior to, the bifurcation of the common carotid artery. It is not a gland in the usual acceptation of the term, but appears to belong to the sympathetic nervous system and to the chromaffin group. It is best developed in early fetal life and gradually disappears in later life. If it remains it is liable to change into a tumor presenting evidences of malignancy. The function of this ganglionic mass is not known. Winslow also says: "That this structure is prone to evil is shown by the ever-increasing number of 'carotid tumors' that are being reported. These cases occur with practically equal frequency in males and females and are found in almost the same ratio in the decades from 20 to 60. A few cases have been reported under 20 years of age and about an equal number above 60. The youngest case reported was 7 and the oldest 74. The type of tumor is usually endothelioma or perithelioma, which is generally benign or but slightly malignant at first, but if not removed tends to become cancerous."

The symptoms seem to be quite indefinite. Winslow finds that generally there are no distinctive subjective symptoms, though there may be alteration of the voice from pressure on the recurrent laryngeal nerve, cough, slight dysphagia, radiating pains, or a sense of discomfort or tenderness. Sometimes there is an irregularity of the pupils from pressure on the cervical sympathetic ganglia. "Usually the patient seeks advice on account of a slow-growing lump in the upper part of the neck, which has either taken on a more rapid growth or has increased gradually to such an extent as to produce deformity and to cause embarrassment." The growth is occasionally rapid, but there is generally a history of a lump that has been present for several years, and when advice is sought it may be as large as a pigeon's egg or a hen's egg. The tumor is single, egg-shaped, and usually unilateral; but at least three cases of bilateral carotid tumor have been reported. The location of the tumor is opposite the thyroid cartilage and may extend upward to the base of the skull or downward toward the clavicle. The tumor is smooth, firm, movable laterally but not vertically, and sometimes there is an upheaval pulsation with bruit and thrill, from its relation to the carotid arteries. The growth is originally encapsulated and does not infiltrate the surrounding tissues until malignancy is well advanced. Sometimes, as in Mathews' case, these growths are extremely vascular.

Positive diagnosis has seldom been made before operation; but Winslow finds that the condition is being recognized more frequently as its clinical features are becoming better known. He made a tentative diagnosis of carotid tumor before operation in the case he reports, though he admits that he was not sure of the diagnosis until the tumor had been exposed and he saw its relation to the carotid artery. Carotid tumor has been most frequently mistaken for a tuberculous lymph-node, aberrant thyroid, carcinoma, or sarcoma of glands. In Winslow's opinion, "a single, slow-growing, firm, smooth, discrete, usually painless oval lump, more or less fixed, situated in the superior carotid triangle opposite the thyroid cartilage and anterior to or under the sternomastoid muscle, should always cause us to suspect a neoplasm of the carotid body."

The treatment is operative; but operation should be undertaken only by the expert since there is danger of wounding the hypoglossal, recurrent laryngeal, or pneumogastric nerves, and since ligation of the common carotid and internal jugular, with its attendant dangers, cerebral and otherwise,

may be necessary. In some cases the growth may be shelled off the vessels, though danger of recurrence is much greater than when the vessels and tumor are removed *en masse*. Keen's statistics showed a mortality of 27 per cent.; but Winslow found that in the entire 59 cases in which the tumor has been reported extirpated there have been 12 deaths, a mortality of about 20 per cent. Since the only hope of removing these growths without ligation of the carotid and without danger of recurrence is in the early period of their development, while they are firmly encapsulated and loosely attached to the vessels, general practitioners as well as surgeons should bear them in mind when consulted by one having a deep, fixed tumor in the carotid region and promptly refer the patient to a surgeon competent to deal with it.

IS LAUDABLE PUS LAUDABLE?

It is not so long ago that we used to speak much of laudable pus, not so long ago in the history of medicine, that is. Those of us who are young in years—we are all young in spirit—remember our professor of surgery saying during one of his first lectures something like this, "Formerly it was not believed that a wound was healing properly unless a quantity of typical creamy pus was present. This was called 'laudable pus,' because it was thought that it was really beneficial. Now we know that for a wound to heal in an ideal manner there should be no pus whatever." As a matter of fact, the old-time doctors were not so far off after all. This kind of pus to which they referred was usually a staphylococcus infection, had little tendency to spread, and showed an active resistance of the tissues to the infective organism. So that while as a purely academic proposition it may be conceded that the ideal wound is a pusless wound, still in actual practice it is sometimes better to let the pus alone.

Of this opinion are Drs. Donaldson, Ament, and Wright, who published a report in the *British Medical Journal* for August 26. These doctors entered upon their military practice firm in the belief that pus has no place in the modern surgeon's scheme of things; experience taught them that in many cases the pus should be left alone, and the patient would get along the better for it. There did not seem to be any delay in healing, the patient's general condition remained good, and his pulse and temperature stayed down. The patients themselves were put in a more cheerful frame of mind by doing away with frequent, painful dressings, and the tissues were allowed to remain in a state of rest, most favorable for healing. There is, to be sure, an esthetic objection in the odor arising from the seldom-dressed septic-case, but this would seem to yield in importance to other considerations.

The writers quote a number of cases illustrating the success of their method, which is, briefly, as follows: The wound is thoroughly opened up, irrigated, then packed with gauze containing saline tablets and covered with a moist dressing. About a week intervenes before redressing. Sometimes symtoms arise which appear alarming, and self-restraint and confidence are necessary. Unless increased swelling, a persistently rising pulse, tenderness, and edema arise, the policy of non-interference should be maintained. Many objections to this method have, of course, been made, say its advocates, but the only one which does not apply equally to the other methods is the one based on smell, and this may be partially invalidated in various ways. Concluding, the writers say that they are aware that a method so diametrically opposed to current practice will meet with harsh criticism, chiefly on theoretical grounds, but they urge, and with a show of reason, that their method is not founded on theory, but on practice, and should be given a thorough practical trial by any sceptics before being discarded.

It is just such methods as these that American physicians can learn with benefit. In the event of war, which recent history has taught us is by no means impossible, we should have large numbers of wounds to attend to, most of them being frankly septic. We should be confronted with the problem of curing these cases as completely and as quickly as possible, and at the same time the procedure which would require the least work on the surgeon's part would be the method of choice, for there is no doubt that such an eventuality would find our profession fearfully overworked.

EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.

The subject of early diagnosis of pulmonary consumption is becoming more and more complex. One sanatorium expert regards it as almost fatal to wait for bacteriological and stethoscopic signs and lays stress solely on the pulse, evening fever, cough, and slight wasting, this syndrome often antedating the resources of physical diagnosis. A second expert takes the view that in many so-called incipient cases in which recovery occurs the patients never had tuberculosis, but have become objects of suspicion by sojourn in the sanatoria. There appears to be warrant for almost any extreme of opinion because of lack of standardization of diagnostic criteria. The discovery of bacilli in the sputum is still the only criterion, but since it is of limited prognostic value it must have backing of some sort. At present the Schrön-Much granules are the object of search of the bacteriologist, and if these are absent tuberculosis is regarded in some quarters as practically excluded. A great advance was made in this field when very small quantities of sputum were made to yield positive finds. The chance of finding bacilli varies directly with the amount of sputum available for repeated tests, and with the amount of time at the bacteriologist's disposal. From the latter viewpoint any method which can cut short the time without prejudice to thoroughness should be welcome to the clinician.

In *Il Policlinico* for July 9, Martelli publishes the following method for early recognition of bacilli in the sputum when expectoration is almost absent: 1. Give the patient up to one gram of iodide of potassium daily, with expectorants (senega, ipecac) for two or three days. 2. Collect from 100 to 200 c.c. of sputum and treat it in the usual manner with antiformin in equal parts, leaving it from 2 to 4

hours in the thermostat. 3. Centrifugalize with high velocity, decant, and wash with saline solution, repeating this several times. 4. Make three very thin smears on slides, fix, and color with Giemsa stain in order to reveal ordinary bacteria, cell residues, etc. 5. Stain a slide with Ziehl's carbol-fuchsin with consecutive decoloration with acid and alcohol; another slide may be treated by Much's method, reserving a third one in case of failure of one or the other method, or of a double negative result. This technique may reveal the presence of a few isolated bacilli and of a few clusters of Schrön-Much granules and thus establish a diagnosis of incipient pulmonary tuberculosis. The author has been able to make this diagnosis in cases which clinically were regarded as examples of pretuberculous fever, Addison's disease, febrile anemia, chlorosis, etc.

Precisely the same technique may be used successfully in glandular tuberculosis by substituting borings from the glands for sputum.

Operative Treatment of Chronic Obstructive Jaundice.

There is little doubt that in cases of obstructive jaundice operation is generally if not always called for. Drs. Erdmann and Heyd, writing in the *American Journal of the Medical Sciences* for August, 1916, say that in most circumstances any operative intervention will be in the nature of a palliative procedure to provide drainage for the biliary secretion or excretion. Given an obstruction in the common duct or its terminus, the ampulla of Vater, there is the choice of a variety of operations. The simplest is external drainage by means of a cholecystostomy. Such an operation entails a rapid loss of bile salts and body fluids and should not be the procedure of choice, but an anastomosis between the gall bladder and some nearly approximate portion of the intestine is physiologically and anatomically correct. However, the choice of a particular operation will depend upon a number of factors such as (1) the physiological efficiency of the procedure; (2) the ease of technical accomplishment; (3) the relative immunity from ascending infection; and (4) the immediate and remote effect upon the patient's metabolism. The following are the conclusions reached by the author of the article referred to: (1) All cases of obstructive jaundice are entitled to operative consideration. There is a certain definite percentage of cases that are cured because there has been a mistake in the diagnosis. (2) Any of the above operations are not prohibitive, considering the severity of the disease and its hopeless outlook. (3) The immediate relief from itching, in addition to the prolongation of life, is an exceptionally strong argument for operation. (4) Operation obviates the development of "pressure pain" from increasing distention of the biliary apparatus. (5) These operations are advised solely as palliative procedures, and as such their purpose must be clearly understood.

The Scrotal Sign in Pellagra.

The commonly held impression of the onset of pellagra is that it begins with erythema of some exposed part of the skin, usually the backs of the hands. Some recent investigations* seem to disprove this theory and call attention to a new sign which in all the cases studied appeared first and would have been overlooked had it not been for the peculiar circumstances of the investigation. These were the production of pellagra experimentally in previously healthy adult males. As a means of checking up the conclusion that a restricted diet, chiefly of carbohydrates, is responsible for pellagra, a record of the experimental production of this condition in healthy persons by such a diet is extremely valuable. Such an experiment is recorded in a recent Public Health Report. At the farm of the Mississippi State Penitentiary, about 8 miles east of Jackson, Miss., about seventy to eighty convicts were stationed. Twelve of these volunteered for experiment and were put on a restricted diet. This consisted of biscuits, mush, grits, gravy, syrup, sweet potatoes, and collards. The twelve volunteers and twenty "controls" were kept under constant observation, their entire skin surface being examined every day. About five months after the beginning of the experiment the first symptoms appeared. In every case the first appearance of the lesion was on the skin of the scrotum. Later lesions appeared on the backs of the hands and in one case on the back of the neck. In view of the fact that these experiments afforded, probably for the first time, an opportunity to observe cases of pellagra from the beginning and that in all these cases the scrotal sign was the first one, it would naturally suggest the examination of the scrotum as a routine measure in physical examinations made in the districts where pellagra is rife. It will next be necessary to perform the same experiment on a group of women to determine the corresponding initial lesion in that sex.

News of the Week.

Centralization of Red Cross.—The demand for the courses of instruction conducted under the direction of the National Committee on Red Cross Nursing Service has developed so rapidly that some of the Red Cross chapters in the larger cities have organized teaching centers. This centralization of instruction has been found to result in greater economy, more uniform teaching, better control, and better classification of those who complete the courses. Centers have already been established in Cincinnati, Chicago, Los Angeles, and New York. To facilitate the dissemination of information about the needs of European war sufferers among its chapters, the American Red Cross has established a special bureau in the Metropolitan Tower, New York.

Status of Red Cross Base Hospital Units.—The American Red Cross has recently issued a circular defining the status of the base hospitals which have been or are being organized under the Department of Military Relief, and pointing out that these have a strictly war-time purpose, and are not available for civilian relief after disasters other than war. The statement says: Base hospitals are purely military units, organized at the request of the Medical Departments of the Army and Navy, and equipped with a view to the needs of the military service only. In both organization and equipment they are too massive and too immo-

* "Experimental Pellagra in the Human Subject Brought About by a Restricted Diet," By Joseph Goldberg and G. A. Wheeler, U. S. Public Health Service.

bile for civilian relief work. The muster-in pledge contemplates only national service, when called into the military service of the United States; and it has been decided by the Judge Advocate General of the Army that the law does not authorize the calling out of these units by the President except in time of war or when war is imminent.

Health Insurance.—A public meeting on Compulsory Health Insurance will be held under the auspices of the Committee on Medical Economics of the Medical Society of the State of New York at the Academy of Medicine, 17 West Forty-third Street, New York City, on Thursday evening, November 23. The speakers will include men of national reputation and experts on Health Insurance.

Health Insurance in Canada.—The *Weekly Bulletin* of the Department of Health, New York, states that the plank for the compulsory health insurance of wage earners has been adopted by the National Liberal Party of Canada as a part of its platform for the election following the conclusion of the war. It is anticipated that the Conservative party will adopt a similar progressive program, and that health insurance laws will be enacted in Canada in the early days of reconstruction. "Compulsory health insurance of wage earners, based on joint contributions from the State, employers, and employees, has been established in Germany, Austria-Hungary, Russia, Great Britain, Holland, Norway, Roumania, and Serbia. In most of these countries both cash and medical benefits are provided for the insured workers, and effective campaigns for the prevention of sickness have become general," says the *Bulletin*. In this country a bill has been drafted by the American Association for Labor Legislation, and will be introduced next year in more than twenty State legislatures.

Harvey Society.—The second lecture of the present series of the Harvey Society will be given at the New York Academy of Medicine, 17 West Forty-third Street, on Saturday evening, November 4, at eight-thirty, by Dr. F. M. Allen of the Hospital of the Rockefeller Institute. The subject of the lecture will be, "The Rôle of Fat in Diabetes."

Personals.—Dr. Charles Lincoln Furbush of Philadelphia has been appointed special assistant to the American Embassy at Berlin, as medical inspector of prison camps in Germany.

Dr. Fernando Calderon y Roca, a Filipino, has been named to succeed Dr. William E. Musgrave as medical director of the Philippine General Hospital. Dr. Musgrave's resignation was recently accepted by the Governor-General.

Dr. Harry Vaughan of Morristown, N. J., is a candidate for the governorship, standing as the joint nominee of the National Prohibition and the Local Option parties.

Dr. Walter H. Brown has resigned as State epidemiologist of Massachusetts, and will preside as executive officer of the Board of Health of Bridgeport. Conn. It is planned to establish in Bridgeport a series of clinics modeled after the outpatient department of the Massachusetts General Hospital.

Prof. John Scott Haldane of the University of Oxford, who came to this country last month, and has delivered several lectures here, sailed from New York on October 27 for London.

Gifts to Charities.—By the will of the late Mrs. Emily Lavanburg of New York, bequests of $10,000 each are made to Mt. Sinai Hospital, the Home for Aged and Infirm Hebrews and the Montefiore Home, New York.

A Public Clinic in Genito-urinary Diseases will be held every Thursday evening at 8.30 o'clock by Dr. Abr. L. Wolbarst, at the West Side German Dispensary and Hospital, 328 West Forty-second Street, New York. The clinics will begin on November first, and will end in April. Physicians and medical students are cordially invited.

Clinical Society of the New York Polyclinic Medical School and Hospital.—A regular meeting of this society will be held in the surgical amphitheater of the Polyclinic, 341 West Fiftieth Street, on Monday evening, November 6, at 8.30 P. M. The discussion will be on goiter and the thyroid gland.

Maine Medical School.—The Medical School of Bowdoin University, Brunswick, Me., began its ninety-seventh annual course of instruction on October 16, with a registration of 55. The requirements for admission were raised this Fall to two years of college work, including physics, chemistry, biology, and either French or German. A number of changes have been made in the faculty.

Emmanuel Movement.—The status of what is known as the Emmanuel Movement, an employment of the principles of psychotherapy by the clergymen of the Episcopal Church, may shortly be determined before the Supreme Court of the State of California. The Rev. Parker Boyd of San Francisco, said to be head of the Emmanuel Health Institute of that city, was recently arrested on a charge of diagnosing without a medical license, and the case will probably be taken before the highest court. The health institute is described as part of the Emmanuel Movement, devoted to suggestive therapeutic treatment.

Ambulance Work on Film.—A private view of the film of the American Ambulance Field Service, "Our American Boys in the European War," was recently given in New ork. The picture shows every detail of the work of the young American college boys in caring for the wounded.

Hospital Destroyed.—A fire in the Roman Catholic Hospital at Farnham, Quebec, on October 26, completely destroyed the building and resulted in a serious loss of life, the estimate being that five children, eight women, and six men had perished.

Healthy Jersey.—During the month of September there were reported in New Jersey 2,139 cases of communicable diseases, as compared with 3,558 during August, a decrease of 1,419. Cases of infantile paralysis dropped from 2,114 in August to 957 in September; typhoid fever showed a slight increase, 331 cases as against 287, but both scarlet fever and diphtheria declined.

Medical Relief for Palestine.—The Zionist Committee, New York, has secured permission from the Department of State for the sending of a medical unit and a large quantity of drugs to Palestine, the drugs to be shipped on the Syrian relief ship which is to sail shortly under the joint auspices of the Syrian Committee and the American Red Cross. The medical unit, which will be sent as soon as sufficient funds are collected, will consist of ten doctors and five nurses, and will deal with the epidemics of typhus and cholera now raging in Palestine.

Birth Control Clinic.—After spending several days in a still hunt, the New York police succeeded

on October 26 in locating and raiding the birth control clinic established by Mrs. Margaret Sanger in the Brownsville section of Brooklyn. Mrs. Sanger and her assistant were arrested and held in $500 bail each.

Death of Centenarian.—Mrs. Mary Simpson Clingman of Cedarville, Ill., died at her home on October 23, within two months of her 107th birthday. She leaves four children, the oldest 74 and the youngest 65.

Barnert Hospital Dedicated.—The new Nathan and Miriam Barnert Memorial Hospital, erected at a cost of $150,000, and presented to the city of Paterson, N. J., by Mr. Nathan Barnert, as a memorial to his wife, was dedicated on October 24. The hospital covers an entire city block at Broadway and East Thirtieth Street.

Beriberi Case.—The Board of Health of New Bedford, Mass., announced on October 24 that a case of beriberi had been discovered in the city. The patient arrived in this country recently on a packet from Cape Verde.

Civil Service Examinations.—Open competitive examinations will be held in various places in New York State on December 2, 1916, for the purpose of filling vacancies in the positions listed below. Full particulars may be obtained by application to the State Civil Service Commission, Albany, N. Y.

Women physician, regular or homeopathic, State hospitals and institutions. Salary, $1,000 to $1,500 and maintenance. Candidates must be licensed medical practitioners of the State of New York, and must have had at least one year's experience on the medical staff of a hospital or three years' experience in the general practice of medicine.

Physician, State prisons and reformatories. Salary, $2,000 without maintenance. Examination open only to men who are licensed medical practitioners in this State, who are not less than 25 years of age, and who have had at least three years' practice. It is expected that one appointment will be made at Sing Sing in the near future.

Deputy medical examiner, Bureau of Deportation, State Hospital Commission. Salary, $3,500. Applicants must be physicians licensed to practice in New York State, and with not less than five years' experience in the practice of Medicine. Minimum age limit, 30 years. Applicants will be expected to have a knowledge of the Insanity Law and experience in the care and treatment of the committed or alleged insane in the New York State Hospitals, or elsewhere, or knowledge and experience of the problem of the alien insane and their deportation.

Dentist, Monroe County service. Open to men only. Candidates must be graduates of a recognized dental college, and eligible to enter the State licensing examination. A vacancy exists at the Iola Sanatorium at $60 per month.

American Medical Editors' Association.—The Forty-seventh Annual Meeting of this Association was held at the Hotel McAlpin, New York City, October 25 and 26, under the presidency of Dr. Edward C. Register of Charlotte, N. C. The report of the secretary shows the affairs of this organization in a thriving condition both financially and as regards membership. Twenty-five applications for membership were received during the past year. In his presidential address, Dr. Register spoke on "The Freedom of the Medical Press," making a strong plea for the independently owned and edited medical journal, and sounding a word of warning against the tendency to put medical journals officially and irrevocably under the control of medical organizations. An entire session was devoted to a symposium on "The Duty of the Medical Editor in Harmonizing the Doctor with Medical Legislation and Its Administration, and in Securing His Aid, Coöperation, and Support in Framing and Enforcing Proper Laws, with Special Reference to Antinarcotic Legislation." Dr. C. F. Taylor of Philadelphia gave a résumé of the antinarcotic laws in the various States, which showed that in a number of States the law forbids the dispensing of narcotics by the physician. He said: "Medical editors do not seem to have grasped the idea now being fought out in regard to the dispensing of remedies by physicians. One of the errors they have fallen into is to regard dispensing as a method of selling drugs. That is totally wrong. It is simply the idea of preserving to the doctor his right to dispense remedies to his patients as he desires to do so. The question is whether the doctor shall be allowed to carry a medicine case and have the customary supply of medicines in his office, or whether his armamentarium shall be reduced to a prescription pad. Many times the doctor must be prepared to do something for his patient immediately. To go empty-handed, and write a prescription for the patient to get the medicine when the druggist pleases, will leave many a patient in a bad situation." A dramatic feature of this discussion was the plea of an aged physician, who had for thirty-five years been a morphine habitué, and who had taken thirteen cures, without avail, for mercy and justice for others in a like plight. He said that society condoned the weakness of a man who was a slave to whiskey, while it made of the man who was addicted to the use of a drug a social outcast, without ever attempting to understand his disease. What was now needed was a better understanding of the evil and a wiser course of dealing with it than by the passage of unreasonable laws. Judge C. M. Collins of the Court of Special Sessions told the story of the criminal and the underworld, as he saw it from the court room, and said that drastic laws were needed and had come to stay. The judge, however, could interpret the law with discretion, and the legitimate practitioner of medicine had little to fear. As for those who used their profession as a cloak under which to carry on illicit traffic in drugs, the medical profession should devise some way of dealing with them by which their licenses would be revoked. He suggested an organized method, such as the legal profession now had, for dealing with offenders against the rules and regulations governing the practice of law. Mr. B. C. Keith, representing the Department of Internal Revenue, explained that the Bureau which he represented was engaged simply in enforcing the Harrison law, and that they needed the support of all physicians. He stated that a conservative estimate placed the number of drug habitués in the United States at 1,000,000. Dr. Ernest F. Bishop of New York City urged the study of the problem of drug addiction from the clinical side. His experience showed that the solution of the problem rested with the medical profession and the medical journals, who must teach that drug addiction is a disease which belongs to the province of internal medicine, and can be dealt with successfully from this standpoint.

Among other papers read and discussed were the following: "Latin and Greek as Prerequisites of the Study of Medicine," by Dr. Abraham Jacobi of New York; "The Responsibility of American Journalism," by Dr. George M. Piersol of Philadelphia; "Book Reviews in Medical Journals," by Dr. H. S. Baketel of New York; "Editorial Individuality," by Ira S. Wile of New York; "The Editor's Prerogative in Editing Original Contributions," by Dr. H. Edwin Lewis of New York; "The Medical Journal and Its Sphere in Medical Progress," by Dr. A. S. Burdick of Chicago; "Independence in Medical Journalism," by Dr. Llewellyn Eliot of Washington, D. C.; "The Function of a State Medical Association Journal," by Dr. George W. Kosmak of New York; and "The Editorial Collaborator," by Dr. Samuel F. Brothers of Brooklyn.

The following officers were elected: *President*, Dr. George M. Piersol of Philadelphia; *First Vice-president*, Dr. Charles Wood Fassett of St. Louis; *Second Vice-president*, Dr. Robert M. Green of Boston; *Secretary and Treasurer*, Dr. Joseph MacDonald, Jr., of New York.

The annual banquet of the Association was held at the Hotel McAlpin on the evening of October 26.

Medical Society Elections.—VERMONT STATE MEDICAL SOCIETY: Annual meeting at St. Johnsbury on Oct. 12 and 13. Officers elected: *President*, Dr. Clarence H. Beecher, Burlington; *Vice-president*, Dr. Charles W. Howland, Shoreham; *Secretary*, Dr. William G. Ricker, St. Johnsbury; *Treasurer*, Dr. E. H. Martin, Middlebury.

NEW MEXICO MEDICAL SOCIETY: Annual meeting at Albuquerque on October 13 and 14. Officers elected: *President*, Dr. C. S. Losey, East Las Vegas; *President-elect*, Dr. John W. Kensinger, Roswell; *Vice-presidents*, Dr. Charles A. Frank, Albuquerque; Dr. F. H. Crail, East Las Vegas; and Dr. Hugh V. Fall, Roswell; *Treasurer*, Dr. Frank E. Tull, Albuquerque; *Secretary*, Dr. R. E. McBride, Las Cruces.

HENDERSON COUNTY (TENN.) MEDICAL SOCIETY: Annual meeting at Lexington on October 11. Officers elected: *President*, Dr. William I. Howard, Wildersville; *Vice-presidents*, Dr. J. P. Joyce and Dr. J. B. England; *Secretary*, Dr. Samuel T. Parker, Lexington.

ST. LUKE'S GUILD OF CATHOLIC PHYSICIANS (Boston): Annal meeting at the Carney Hospital, Boston, on October 18. Officers elected: *President*, Dr. John T. Bottomley; *Vice-president*, Dr. John R. Slattery; *Secretary-Treasurer*, Dr. John J. Sullivan.

Relation of the Chemist to the Public Welfare.—A meeting of the New York Section of the American Chemical Society will be held at the Chemists' Club, 50 East Forty-first Street, New York City, at which the following papers will be read: "The General Problem of Public Service Training," by Prof. Charles A. Beard of Columbia University and of the Training School for Public Service; "The Status and Compensation of the Chemist in Public Service," by Prof. Frederick E. Breithut of the College of the City of New York; "The Chemist in Public Service," by Dr. Harvey W. Wiley; "The Chemist in the Service of New York City," by Dr. Otto H. Klein, director Central Testing Laboratory.

New Societies Formed.—The New England Surgical Society, which was organized early this year with a membership of 75 representative surgeons from the six New England States, held its inaugural and first annual meeting in Boston on October 5, 6 and 7. The sessions were held at the Harvard Medical School, at several of the Boston hospitals, and at the Copley-Plaza. During its first year the officers of the society have been as follows: *President*, Dr. Samuel J. Mixter, Boston; *Vice-president*, Dr. John B. Wheeler, Burlington, Vt.; *Secretary-Treasurer*, Dr. Philemon E. Truesdale, Fall River, Mass.; *Executive Committee*, Dr. John W. Keefe, Providence, R. I.; Dr. Joseph M. Flin, New Haven, Conn.; Dr. Lyman Allen, Burlington, Vt.; Dr. Herbert L. Smith, Nashua, N. H.; and Dr. William L. Cousins, Portland, Me. The society will meet once a year in various cities in New England.

The alumni of the College of Medicine of Fordham University, New York, at a meeting held in this city on October 27, formed an association. The following officers were elected: *President*, Dr. James McSweeney; *Vice-president*, Dr. John J. Sheridan; *Secretary-Treasurer*, Dr. Francis McGovern. Father J. Tiernan addressed the members of the association on "The Menace of Birth Control."

Obituary Notes.—Dr. LOUIS MCLANE TIFFANY of Mount Custis, Va., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1868, and a member of the Medical Society of Virginia, the Medical and Chirurgical Faculty of Maryland, the Baltimore City Medical Society, and the American Surgical Association, professor emeritus of medicine at the University of Maryland, and consulting surgeon of Johns Hopkins Hospital, St. Joseph's German Hospital and the Church Home and Infirmary, died from heart disease at his home, on October 23, aged 73 years.

Dr. DAVID BRADEN KYLE of Philadelphia, a graduate of Jefferson Medical College of Philadelphia in 1891, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania and the Philadelphia County Medical Society, died at his home on October 23 from pneumonia, after a short illness, aged 53 years. Dr. Kyle was professor of laryngology at the Jefferson Medical College, and a member of the American Laryngological Association, the American Laryngological, Rhinological and Otological Society, the American Otological Society, the College of Physicians of Philadelphia, the Puget Sound Academy of Ophthalmology and Oto-Laryngology, the Philadelphia Pediatric Society, the Pathological Society of Philadelphia, the Philadelphia County Medical Society, and the Medical Society of the State of Pennsylvania, and also a fellow of the American Medical Association.

Dr. ALEXANDER A. UHLE of Philadelphia, a graduate of the University of Pennsylvania, School of Medicine, Philadelphia, in 1898, died suddenly following an injection of cocaine preliminary to an operation on the tonsils on October 21, aged 42 years. Dr. Uhle was a member of the College of Physicians of Philadelphia, the American Medical Association, the Medical Society of the State of Pennsylvania, the Philadelphia County Medical Society, the Philadelphia Academy of Surgery, the American College of Surgeons, the American Association of Genito-Urinary Surgeons, the American Urological Association, the Philadelphia Genito-Urinary Society, and the Pathological Society of Philadelphia. He was assistant instructor in genito-urinary diseases in the University of Pennsylvania, assistant surgeon to the dispensary for genito-urinary diseases of the University Hospital, assistant genito-urinary surgeon to the Philadelphia General Hospital, assistant surgeon to the dispensary of the German Hospital.

Correspondence.

PRONUNCIATION OF POLIOMYELITIS.

To the Editor of the Medical Record:

Sir:—Here in New York somebody imagined that euphonics would be mollycoddled by pronouncing "poliomyelitis" as though it were spelled "pohliomyeleetis"; "pohlio" as in "folio," "eetis" as in "Musketeer." This pronunciation appears to be contagious, and it may give some young phonetist a bad spell. The difference between doctors and educated people is this: erudite folks were spanked in school days if they did not know that in the poliomyelitis question they were dealing with omicron, and not with omega; consequently they now pronounce the first part of the word as it is pronounced in the first part of the line ending with "wants a cracker." The last part of the word when leaving Athens for New York becomes pronounced "itis" with an eye upon the first "i" in sturdy English, although there is equally good authority for pronouncing this "i" like "ee" in "teeth." One may follow his mentor so far as this particular point is concerned.

The public will lose that confidence in doctors which it should not have had in the first place, if we take liberties with the property of the English language. In professional circles we know that not one gynecologist in five can pronounce the name of his specialty correctly. We may understand that to mean that the other four are equally careless in their diagnoses, and likely enough to treat a flexion of the uterus by mechanical means when the autonomic ganglia of a susceptible patient responding to distant peripheral irritation are in need of belladonna only. That is a trade secret, and the public willingly goes on paying bills for work that should not be done. When it comes to a matter of pronunciation of a word that is in everybody's mouth, however, a sapient public will feel that doctors are not to be trusted with the care of an infection if they cannot be trusted with a word which enters at the very threshold of a case.

Robert T. Morris, M.D., F.A.C.S.
616 Madison Avenue, New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE PROPOSED NEW CENTRAL MEDICAL BOARD—PROTEST BY DUKE OF BEDFORD—DIFFERENCE BETWEEN "MEDICALLY UNFIT" AND "NOT LIKELY TO BECOME AN EFFICIENT SOLDIER"—DUTIES OF RECRUITING AND APPROVING OFFICERS—SELECTION OF MEN FOR R. A. M. C.—HEALTH OF LONDON FOR 1915.

London, October 7, 1916.

The Duke of Bedford has made a vigorous protest against the government's proposal to set up a new Central Medical Board, and he gives an illustration of the way in which recent alterations in the recruiting forms permitted an epileptic to be enlisted and posted to a battalion; he served with the colors for 158 days, spent about 90 days in hospital, and on one occasion had an epileptic fit at physical drill. He was discharged from the army as "not likely to become an efficient soldier"—his character marked "good." Since his discharge his general health has further declined, his fits increasing in frequency so that he cannot resume his former occupation. If he had been discharged as "medically unfit" he would have been entitled to a pension, but not as it is. The duke remarks that it is the duty of medical boards, recruiting officers, and approving officers to guard taxpayers from financial liability arising from the enlistment of men whose health shows that in a few months they will be discharged in a worse state than on entrance. Unsound men on discharge have a claim for compensation for injury to their health and wage-earning capacity while in the service. These unsound men who are sure to have spent part of their time in hospital are a dead loss to the State for they deprive sound men of training and armament, or occupy beds wanted for men invalided from the front. The duke objects that this will only be a source of expense and give no relief to taxpayers for past failures of the existing system, and further he adds that these boards and officers are paid to prevent men who can only become a burden on the public purse from being compelled to serve in the army. He asks why when such officers fail in their duty should the whole cost be thrown on the taxpayers and says it is a sound principle that those who run up the bill should contribute toward its payment. They can easily be identified, as the names of the officers responsible for their enlistment appear on different army forms. The local committee should have the power of compelling the attendance of approving officers to explain the circumstances under which unfit men were enlisted, and, if no satisfactory explanation is given, of recommending that the offending officers should contribute from their pension, pay, or allowances to the compensation that may be awarded.

It is suggested that the position of the central medical war committee should be defined in the military service bill now before Parliament and in any other measure by which it is affected. At present doctors who enroll do so through the committee which selects out of the whole number men as required by the R. A. M. C. It seems of the first importance that under compulsory service the same arrangement should continue and that the selection of *unenrolled* medical men should be entrusted to the central medical war committee, and this in justice both to the profession and to the civil population.

The medical officer of the London County Council reports that the health of the metropolis for 1915 does not compare favorably with recent years, not so much on account of any influence of the war, as owing to increase of deaths at relatively high ages, attributable no doubt to a prevalence of influenza and of other respiratory diseases during the winter months.

The marriage rate of London for 1915, assuming the population to be four and one-half millions, works out at 25.9 per 1,000 living—higher than any previous year. This rate has been slowly increasing annually since 1908, but the bulk of the increase last year must be attributed to the war. It is probable, however, that many marriages registered in London were not residents here. The birth-rate which has been falling for a number of years past was 23.6 in 1915 as compared with 24.3 in 1914 and 25 in the period 1909-13. Discussing the continuous fall in the birth-rate for the past 40 years, the medical officer says that a theory which ascribes it to a "change in the moral tone of the community and to the artificial limitation of families has met with some acceptance." Against this one of the most cogent arguments is the fact that the fall is widespread throughout Europe and affects certain other civilized communities.

8. The Ileocecal Valve and the Chronic Intestinal Invalid. John Bryant.

1. **Surgery of the Thyroid Gland.**—C. A. Porter analyzes 185 cases of goiter in hospital and private practice of which 85, showing definite Graves's disease or hyperthyroidism present, or very definite in the immediate past, were subjected to operation. In these 85 cases there were 31 ligations and 19 hemithyroidectomies; in 17 the right lobe was removed with ligation of the vessels on the left; in 18 the major portion of both lobes, leaving a bit of the upper or lower poles, and a posterior strip of the gland. In the writer's opinion partial lobectomy is a more severe and bloody operation than hemithyroidectomy, but he feels that it is followed by more immediate improvement and that the danger of recurrence is less. Of these 85 cases operated upon 20 are absolutely cured, 18 much improved, 4 not improved, and requiring further operation; 16 have not reported. Medical treatment of the cases not subjected to operation is discussed and the conclusion reached that if, after a patient has had a reasonable course of rest, medical treatment, and *x*-ray treatment, the symptoms persist, operation should be advised. Among wage-earners, who cannot give up the time, and in the chronic cases, in which the disease has advanced too far to allow of delay after a preliminary rest, operation should be performed. Whether this be a preliminary ligation, or lobectomy under local or general anesthesia, must be determined in each case. Finally, in chronic cases, in which there is doubt as to whether the patient is suffering from existing toxemia or has been poisoned irreparably by the disease, modern tests, of which basal metabolism is probably the most important, will aid the surgeon much in deciding for or against operation.

2. **Recent Advances in the Knowledge of the Active Constituent in the Thyroid; Its Chemical Nature and Function.**—Edward C. Kendall recalls that about eighteen months ago he reported the isolation from the thyroid of a crystaline compound containing 60 per cent. iodine. Since that time he has perfected the method for its isolation and has studied its chemical property and functions. He has experimented on animals and obtained a large number of results from clinical observations from which it appears that the entire activity of the gland is manifested by the administration of this crystaline compound alone. There appears to be no other substance in the thyroid secretion which acts directly. After the administration of the compound there is no apparent effect for many hours. There is no increased pulse rate or drop in blood pressure. However, if the thyroid hormone and amino acids are injected simultaneously, the pulse rate is enormously affected, and even death may result, due to the apparently great increase in metabolism going on in the animal. It appears very probable that the thyroid hormone manifests its activity by reacting in some way with amino acids.

4. **The Clinical Value of Metabolic Studies of Thyroid Cases.**—Walter M. Boothby states that diseases of the thyroid gland, with their extreme variations in basal metabolism, afford a most striking example of the significance of metabolic studies. Basal metabolism for clinical purposes can be obtained with a high degree of accuracy by collecting, measuring, and analyzing the expired air. In normal persons the basal metabolism rarely varies more than 10 per cent. from a normal figure, depending upon age and sex, when compared by surface area determined by DuBois height-weight curve. Several cases of thyroid dystrophies, in which the basal metabolism was determined, are cited, and these show that in conditions of thyroid overactivity the metabolism may increase to over 100 per cent. above normal, and in conditions of underactivity it may be decreased to 50 per cent. below normal. They have found that the patient's condition, judging from the sum total of the objective and subjective symptoms, correspond very strikingly to the numerical expression of the basal metabolism.

6. **The Treatment of Graves' Disease by the Roentgen Ray.**—Malcolm Seymour writes that they have had under Roentgen ray treatment at the Massachusetts General Hospital 144 cases of Graves' disease, the treatment of most of these having been carried on since August 1, 1915. Of these 144, eighty have been given at least two treatments and all of these have shown improvement, with the exception of seven cases. Nearly all have gained in weight, the average gain having been seven pounds. The pulse rate has been lowered in all but a few cases, the average being twelve beats. The writer outlines his method of treatment and concludes that the advantages of the Roentgen ray treatment are that there are no fatalities; there is no resulting scare, as after operations; it is painless and, if unsuccessful, an operation may be done with less risk, because of the favorable action of the *x*-ray on the thymus gland.

7. **The Excretion of Hexamethylenamine by Damaged Kidneys.**—George Gilbert Smith has been investigating the statement made by Falk and Sugiura that in a number of pathological cases involving the impairment of kidney function, abnormally small amounts of hexamethylene tetramine were excreted. The cases studied, fourteen in number, fell into two groups: (1) the surgical kidneys resulting from renal calculus ob-obstructing prostate, etc., and (2) the medical nephritis of chronic interstitial or glomerular type. As positive evidence on the question of the output of urotropin by infected kidneys, facts are presented drawn from a study of ten cases of undoubted renal disease of this type. In every case urotropin was excreted; in three cases, in a strength of 1 to 10,000; in two, 1 to 30,000; in one 1 to 40,000. It was weaker in the other four although strong enough to give a definite test with Burnam's method. In chronic nephritis of advanced degree, in three cases a diminution in the output of urotropin which would be a serious factor in its employment as a therapeutic agent. Fortunately, in such cases it need seldom be employed. In kidneys damaged by infection, even to a very marked degree, the drug may be excreted in a strength as high as 1 to 10,000. The fact must be borne in mind that, no matter how much urotropin is excreted, it will be useless as a bactericide unless it is broken up into formaldehyde by urine, which is definitely acid.

8. **The Ileocecal Valve and the Chronic Intestinal Invalid.**—John Bryant presents a preliminary note on valvular incompetence, together with a number of case reports demonstrating successful non-surgical therapy in this condition. He states that his personal experience seems to justify the following assertions: (1) In the mild or ambulent group of chronic intestinal cases, the frequency of incompetence may be distinctly

in excess even of the accepted ratio of one to five. (2) When present, incompetence should be treated as an undesirable pathological entity; an entity, however, usually responsive to intelligent treatment. (3) Under adequate medical treatment the patient may be assured at least some degree of improvement, with corresponding alleviation of symptoms; surgery is only secondarily indicated. (4) Medical treatment may even restore the valve to complete competence. (5) The progress and results of treatment are under absolute control through the agency of the bismuth-Roentgen meal and enema. Given a case with a chronic intestinal history, with local pain, coarse crepitation on pressure over the right iliac fossa, excessive gas formation not easily relieved, constipation, stasis, and evidences of toxic absorption and a presumption of valvular incompetence is created, which should be subjected to proof by the *x*-ray.

1. Considerations in the Medical Treatment of Goiter. J. M. Anders says that the medical treatment of goiter must have special reference primarily to the particular clinical variety. For example, if the given case in hand is of the non-toxic form, then iodine and thyroid extract are indicated; if of the toxic type, or exophthalmic goiter, then these medicaments would be for the most part pernicious in their nature. It has always seemed to him to be the part of wisdom to discontinue the iodine in cases in which the thyroid extract is exhibited, on account of failure of the former remedy to bring about a cure. If, however, the dessicated thyroid extract, like the iodine, fails when employed alone, then these remedies should be given simultaneously, their action being almost identical, notwithstanding. Should untoward results follow the thyroid medication, they may be successfully combated by two or three minim doses, thrice daily, after food, of Fowler's solution. Disappearance of goiter should be the signal for the discontinuance of the remedy but a recurrence, however slight, should lead promptly to its readministration. An ointment of biniodide of mercury with massage over the gland favors absorption of the hyperplasia. The treatment of this type of goiter is entirely satisfactory, provided that the condition is recognized early enough, and iodine and other agents recommended are judiciously and promptly employed. Among the prominent causative factors of Graves's disease are emotional excitement, shocks, tuberculosis, rheumatism, syphilis, and intoxication from the intestinal canal, and each of these should receive proper and careful attention. Of the numerous available remedies which have been advocated, two are worthy of mention, quinine hydrobromide and antithyroidin Möbius.

2. The Early Diagnosis of Tuberculosis.—Edward O. Otis treats of this subject and concludes that the diagnosis of early clinical tuberculosis depends upon the careful and painstaking assembling, correlation, and study of the symptoms, together with the evidence of the temperature and pulse and such definite physical signs as can be clearly discerned. The main reliance must be upon the symptoms, the pulse and the temperature. If the physician spent the major part of his time and efforts in studying the symptoms and less upon the attempt to determine uncertain physical signs, fewer cases would slip through his hands unrecognized.

3. Removal of the Third Lobe of a Cystic Goiter.—A. Ernest Gallant reports this operation upon a woman with exophthalmos and the points of interest which led to a report of this case were as follows: (1) The mother and five sisters had goiter and were said to have been cured by medicine; (2) the successive enlargement of the right and left lobes after removal of the middle lobe, with intervals of fourteen and four years, respectively; (3) the aphonia following the second operation, and restoration of the voice after the third operation; (4) the very disagreeable effects when thyroid gland or potassium iodide was administered; (5) the almost uninterrupted discharge from the sinus, and the serious discomfort and "queer feelings" whenever the sinus closed temporarily and the secretion could not escape; (6) the marked diminution of the exophthalmos; (7) the return of a considerable growth of hair in a woman of her age (fifty odd years).

5. Laryngeal Abscess.—Milton J. Ballin reports three cases which he believes are clear examples of laryngeal abscess in which the localized suppuration was situated, as in the majority of instances, on the left side, and in which complete recovery ensued after timely intralaryngeal measures. The main purpose in presenting this subject is to call attention to the infrequency of this laryngeal infection and to emphasize the fact that if it is recognized in time and urgent intralaryngeal measures are adopted, alarming complications can be prevented, and a satisfactory outcome can be obtained in the majority of the cases.

6. Leiomyoma of the Pylorus.—Joseph R. Eastman and Harry K. Bonn state that since the stomach is the primary seat of approximately two-thirds of all gastrointestinal carcinomata, it follows that the diagnosis of any tumor of the stomach is especially important in patients at the cancer age. For this reason they deemed this case of leimyoma of the pylorus, occurring in a man fifty-eight years of age, of sufficient interest to justify its report. It serves to emphasize the following points: (1) Benign neoplasm of the pylorus, especially the myomata, may simulate early carcinoma. (2) Even though the patient has reached the cancer age, benign neoplasm cannot be excluded. (3) Careful sectioning and study of benign neoplasms is necessary for correct diagnosis. (4) The frozen section method cannot be considered an infallible method of diagnosis in this type of neoplasm.

8. Tuberculosis of the Bronchial Glands.—Mary E. Lapham says that the symptoms of tuberculosis of the bronchial glands are caused by the absorption of toxins and by pressure on adjacent structures. The syndrome of tuberculous toxemia is the same as that from the lungs; it is the pressure symptoms that are of particular interest in this form of tuberculosis. Compression of the great vessels may cause cyanosis and edema of the face or even edema of, and hemorrhages into the meninges. It is possible that compression of the superior vena cava may have something to do with the rapidly fatal cases of cynosis, dyspnea, unconsciousness and death, so typically fatal in the bronchial gland tuberculosis of infants. It is also possible that the stasis in the meningal circulation explains the association of tuberculosis meningitis with that of the bronchial glands. As a rule, the meningitis attacks children in apparently good health, and without the knowledge acquired at autopsy there would be no reason for suspecting that meningitis may be secondary to absolutely concealed tuberculous processes in the bronchial glands. Autopsies teach that this association always exists, and

it is inferred that the rapidity of meningeal processes leaves no time for slower developments. Pressure upon the sympathetic may cause irritability of the vasal motors, evidenced by rapid changes from palor to blushes; unequal or unilateral flushing of the cheeks; circumscribed reddening of the second intercostal space, associated with menstrual rises in temperature, a consciousness of unstable heart action, of flutterings and palpitations and quickened pulse; unequal pupils and protrusion of the eyeballs. It is probable that a certain class of gastrointestinal disturbances, characterized by lack or suppression of functional activities, may be due to pressure upon the sympathetic nerves, because these disturbances are present in tuberculosis of the bronchial glands when pulmonary tuberculosis cannot be proved. It is possible that the rhachialgias and intercostal neuralgias preceding the discovery of tuberculosis of the spine may also be caused by enlarged bronchial glands and the infection of the spine may prove to be a secondary condition. Pain in the region of the trapezius is one of the earliest symptoms of tuberculosis of the bronchial glands, as is also pain over the root of the lung. Pressure upon the fibers of the recurrent laryngeal may cause pain in the larynx, laryngospasm, and paralysis of the vocal cord. Changes in the quality of the voice may be one of the very early manifestations of enlarged bronchial glands.

2. Experimentally Transplanted and Transposed Whole Metatarsal Bones.—W. L. Brown and C. P. Brown relate the experiments they have made on dogs and present a number of *x*-ray photographs showing the results obtained. In describing their technique they state that all the dogs' feet and sides for the transplants were prepared after the dog was anesthetized with ether by shaving and painting with full strength tincture of iodine. Following the operation, all wounds on the feet were dressed with a liberal quantity of phenolated gauze and adhesive plaster. The wounds of the thighs and backs were always dressed with collodion and cotton. There were no infections. They state in conclusion that: 1. True transplantation of a part or whole bone into the tissue, where it has no function to perform, is a very different matter from transposing an entire bone into the bed of its fellow of the opposite side. 2. Whole metatarsal bones covered with periosteum, their articular ends included, and transposed into the position occupied by their fellow of the opposite side will live, functionate, and grow, but when truly transplanted under like circumstances into the tissues, where they do not act as an integral part of the bony framework and have no function to perform, they are invariably absorbed, as are all other transplants under like circumstances.

3. The Etiology of Epidemic Poliomyelitis; Preliminary Note.—E. C. Rosenow, E. B. Towne, and G. W. Wheeler. (See MEDICAL RECORD, October 21, page 7739.)

4. Experimental Studies in the Etiology of Acute Epidemic Poliomyelitis.—John W. Nuzum and Maximilian Herzog state that they have obtained from the postmortem material in typical cases of poliomyelitis, from tissues of the central nervous system, tonsils and mesenteric glands, and from the cerebrospinal fluid obtained by lumbar puncture during life, a grampositive micrococcus which grows well on dextrose ascites broth to which a sterile piece of rabbit's kidney has been added—but always better aerobically than anaerobically. Cultures of this organism, when injected into monkeys, produced the typical clinical and pathologic picture of acute poliomyelitis. Definite flaccid paralysis has been produced in dogs and in many young rabbits. In rabbits, however, as others have pointed out before us, there is a variation in the microscopic picture, although many of the changes attendant on the disease in man and monkeys are present in the central nervous system of the rabbit following paralysis. Anaerobic cultures in fluid mediums were passed through Berkefeld filters V, and inoculations of the filtrate into suitable mediums produced a growth of the larger form of the organism seen in aerobic cultures. This would seem to indicate that the organism under anaerobic conditions assumes a form so small that it may pass through the Berkefeld filter. The virus of rabies, as is well known, presents itself in a large form, the Negri bodies, and in the small punctiform granules which can evidently pass the filter. In considering the gram-positive coccus in its etiologic relation to acute poliomyelitis, we must remember that it may act as a carrier of a real ultramicroscopic invisible virus which, together with this micrococcus, might still be transferred in the cultures and passed along in the inoculations. In tissues from the central nervous system of poliomyelitic material preserved in 50 per cent. sterile glycerin, this same micrococcus was alive after a period of thirty-five days, and could be cultivated in pure culture on suitable mediums.

6. Immune Human Serum in the Treatment of Acute Poliomyelitis.—C. W. Wells reports a series of fifteen cases of acute poliomyelitis treated by the administration of immune human serum. He says the administration of immune human serum in acute poliomyelitis is based on the recognized principles of immunity. Because the lesions are not confined to the nervous system, and because the lesions therein consist essentially of perivascular infiltration, intravenous injection of serum appears to be rational procedure, either alone or in combination with intraspinal injection. The intravenous injections of serum should, if possible, consist of doses of from 50 to 100 c.c. or more daily. Following the intravenous or intramuscular injections of serum, spinal fluid should be withdrawn. The intraspinal injection of the serum usually produces an increase in the number of leucocytes with increase in the proportion of polymorphonuclear cells in the spinal fluid. No ill effects have followed the use of serum in this series, either by intravenous or intraspinal injection. In all cases after the intravenous injection, and to a less degree after intraspinal injection, a noticeable improvement usually occurred, which unfortunately in some cases was only transient. The early administra-

tion of the serum is urged, necessitating therefore an early diagnosis of the disease. In severe cases late administration of the serum has produced little if any noticeable influence on the course.

10. **Bacterial Vaccines in the Treatment of Pulmonary Tuberculosis—Impressions as to Clinical Value.**—S. G. Bonney writes that from the data so far obtained his position is that vaccine therapy should by no means be permitted as a routine measure in the treatment of tuberculosis. It has a place as a tentative procedure in a class of cases subject to certain modifying limitations. The careful adjustment of the dosage is vitally important. The results obtained are very uncertain. The gain established in a few cases is, however, impressive. The proportion of cases exhibiting improvement is disappointing. Vaccines not infrequently are shown to possess vast possibilities of injury. In the use of vaccines the attitude of the profession should be one of the utmost conservatism. The cautious employment of baterial vaccines would seem to be appropriate chiefly for persons who fail to show gratifying improvement under conservative management and should be restricted largely to this class of patients. It does not from this follow that vaccines are indicated for all patients who are doing poorly. It may, however, be granted that a demonstrated inability to respond favorably to an intelligent regimen suggests the expediency of specific therapy. On the whole the writer's experience with vaccines in far advanced cases have been disappointing, though he has had one or two instances in which the clinical picture was unexpectedly transformed. The results obtained in a fair proportion of cases in which there was moderate fever have been such as to encourage the further cautious employment of vaccine therapy. This is also true to a large extent in afebrile cases. The greater proportion of such invalids may be expected to make fairly satisfactory progress under proper supervision without recourse to vaccine therapy, but occasional indications for its administration may be found in patients with distressing cough and abundant expectoration. In this class of patients the application of vaccine therapy is sometimes gratifying.

1. **An Inquiry into the Natural History of Septic Wounds.**—Kenneth Goadby presents the second section of this report which was prepared for the Medical Research Committee. In the first section, published in *The Lancet*, July 15, sinus formation and the bacteria present in sinuses and sequestra were considered. This section of the report deals more particularly with vaccine therapy. The incidence of organisms found in the examination of 200 cases of septic wounds, according to the day of examination after wounding, is presented and detailed data with reference to the vaccine treatment given. Out of the total of 200 cases, the malignant edema group of organisms was found in 38 per cent.; the *B. perfringens* in 75 per cent.; *B. hibler* closely follows malignant edema; *B. proteus* and *B. coli* occur in 47 per cent. and 40 per cent. respectively; streptococci in 81 per cent., and staphylococci in 86 per cent. Or it might be stated that anaerobic bacteria were present in some 50 per cent. of badly wounded cases and about 20 per cent. of simple flesh wounds, but the incidence of aerobic bacteria is more common, being met with in about the same relative proportion in all the wounds examined. These wounds were examined at least two days after the injury. The investigation warrants the conclusion that anaerobic bacteria present in a large proportion of the wounds owe their infectivity to the association with anaerobic species, and that among these species the proteus and coli groups and streptococci, some of the latter being facultative anaerobic, are to be regarded as largely concerned in the development of acute septic processes within and around the wounds. Two series of cases were treated, one with vaccine and one without, the treatment being exactly parallel in other respects. The comparison of these series was based on the determination of the duration of the febrile period as determined by temperature charts and by the period during which the patient remained in the hospital. Examining the two series critically, the evidence is overwhelming that the protection afforded by the vaccines was responsible for the absence of secondary hemorrhage in the vaccine cases. No vaccine case developed acute gas gangrene, although the bacterial flora and the physical condition of the wounds were certainly highly potential. There is a difference of ten days in the duration of the fever in favor of the vaccine cases and a difference of 27 days in the hospital. As a result of this investigation the author recommends the following routine treatment: Polyvalent vaccines should be prepared from strains of organisms isolated from the infected wounds, consisting of (1) streptococci (aerobic and anaerobic varieties), sensitized with antistreptococcal serum; (2) *B. proteus;* (3). *B. lactis acrogenes*, and (4) *B. coli.* A mixed vaccine of sensitized polyvalent streptococcus 5,000,000, with *B. proteus* 10,000,000, should be given to all septic cases when admitted, pending the bacteriological report. In cases of gas gangrene streptococcal vaccine combined with *B. proteus* and *B. lactis acrogenes* should be used in strengths of 10,000,000 each. The inoculations as indicated by the bacteriological examination should be repeated on the third day, and the dose raised to 10,000,000 streptococci with 20,000,000 of the appropriate bacilli. Meanwhile, autogenous vaccine may, if necessary, be prepared for special cases when desirable. The author also discusses plating and wiring in septic fractures and states that in severely septic wounds it is not invariably followed by the disastrous results sometimes attributed to this method. When plating and wiring are carried out in immunized subjects the results seem highly satisfactory.

3. **Inquiry into the Clinical and Radiological Diagnosis of Intrathoracic Tuberculosis in Children of School Age.**—Walker Overend and Clive Riviere give this résumé of an investigation undertaken for the Local Government Board of London. The material of inquiry was formed by 61 children between the ages of five and ten, being resident in the district of Bethnal Green. They belonged to three classes, the first containing children with no known source of tuberculous infection in the house, the second exposed to infection of slight or limited extent, and the third to severe infection, one or both parents having in many cases died of the disease. Of 23 children from healthy households, 12
